Norsk Hydro Cell. This cell has been in operation since 1978 and consists of a sealed, brick-lined body that is divided into two separate chambers for electrolysis and metal collection (Fig. 9). Densely packed, cooled graphite anode plates (b) are installed through the roof and double-acting steel plate cathodes (c) through the back wall. Chlorine (> 98 wt %) is collected from a central pipe in the anode compartment. Circulation of the electrolyte (h) is parallel to the electrodes bringing the magnesium metal to the collecting chamber from where it is extracted by vacuum and transported to the foundry. This cell operates on solid or liquid cell feed conveyed continuously or at intervals to the cell at 700 – 720 °C with a current load of 340 – 430 kA. Energy consumption is 13 – 13.5 kW·h per kilogram of magnesium and cell life exceeds five years [81].

VAMI and Titanium Institute Cells. Cell types developed by VAMI (Russian National Aluminium and Magnesium Institute), St.-Petersburg, and the Titanium Institute (State Research and Design Titanium Institute), Zaporozhye, Ukraine, are based on the same principles as the Norsk Hydro cell but operate at 150 – 180 kA and 700 – 740 °C. When operated on dehydrated molten magnesium chloride obtained after reduction of titanium(IV) chloride with magnesium (Kroll process, → Titanium, Titanium Alloys, and Titanium Compounds), the current efficiency is ca. 0.80, with an electric energy consumption of 13.5 kW·h per kilogram of magnesium [23], [79], [80].

A special feature is the hydraulic linking of the cells in a cell room, allowing electrolyte to flow from cell to cell in a "flow line". Cell feed is supplied to the first cell in the line together with

recycled electrolyte, and metal is separated and extracted from the last cell in the line. Significant improvements in performance and productivity are reported [79], [80].

Alcan Multipolar Cell. Alcan Aluminium Limited, Canada, was a magnesium producer in the 1950s, but ceased primary magnesium production in 1959 and has been engaged in technology development since then [34]. Magnesium electrolysis cell designs have been developed in cooperation with a titanium plant (Kroll process) in Japan. New multipolar cell designs have been in operation since 1983 [82]. In such cells a number of bipolar electrodes are placed between the anode and the cathode surfaces. The prime advantage of bipolar cells is the reduction of voltage losses, which in combination with narrow anode – cathode gaps results in an operating cell with very low energy consumption. Special provisions are made to prevent current leaks from bypassing the bipolar electrode system.

The latest Alcan multipolar cell design is the Ex series (Fig. 10) [83]. The average energy consumption of this cell, when operating on high-purity molten magnesium chloride from Kroll titanium production, is 10 – 11 kW · h/kg Mg. The cell operates at 90 – 150 kA with a cell life of about two years [82]. The latest installation of this cell was by Magnola at Danville, Québec, where the cell is connected to Magnola's superchlorinator [60]. The annual output is projected to exceed 2500 t of magnesium per cell.

Ishizuka Cell. The Ishizuka Research Institute, Japan, has developed a bipolar cell that has been used since 1983 for industrial magnesium production in the Japanese titanium industry [35].

Figure 11. Dow cell

Dow Cell. The Dow cell for hydrous cell feed ($MgCl_2 \cdot 2\,H_2O$), shown in Figure 11 was in operation at Freeport, Texas, until 1999. The technology was later licensed to an Australian project [61]. The graphite anodes can be lowered into the cells to compensate for their consumption. Densely packed cylindrical anodes (c) are led through openings in the refractory cell hood (d) and sealed to reduce air leaks. They are centered by insulating ceramic spacers. The development of efficient anode seals to withstand severe corrosive environment and high temperature has been a challenge. Conical cathodes (b) are welded to the steel shell (a) holding the electrolyte. Magnesium metal is conducted by the electrolyte flow to a collecting chamber (e) at the front of the cell. Water in the cell feed is partly flashed off, and partly reacts with $MgCl_2$ to form HCl and MgO. The MgO can react with carbon in the graphite to form CO and CO_2. Graphite consumption is probably 60 – 70 kg per tonne of magnesium. The Dow cell is operated at 700 °C with an estimated current load of 180 kA and current efficiency of ca. 0.8. In comparison with an anhydrous cell feed, the hydrous cell feed increases electric power consumption as well as the formation of sludge and dilute anode gases.

4.2. Thermic Reduction Processes [37], [38], [84]

Carbothermic reduction of magnesium oxide

$$MgO(s) + C(s) \longrightarrow Mg(g) + CO(g)$$

appears attractive but is not used industrially. The main problem is the high reaction temperature (1800 – 2000 °C) and the need for rapid cooling (quenching) of the reaction gases to suppress the reverse reaction back to magnesium oxide [14]. An industrial plant based on carbothermic reduction was operated in the United States during World War II, using natural gas as the quenching medium. The reaction product contained only 50 % Mg metal and had to be processed in a sublimation step to obtain pure Mg metal. In later experimental studies, quenching has been based on rapid adiabatic expansion of the gases [15] or cooling in liquid metal [84].

Calcium carbide was used as a reductant for MgO in England before and during World War II [85].

Industrial *metallothermic processes* for magnesium production are based on the reduction of magnesium oxide with silicon and/or aluminum. Magnesium oxide is provided in the form of calcined dolomite (MgO·CaO), sometimes enriched with calcined magnesite (MgO). The basic reaction of calcined dolomite with silicon is

$$2\,MgO \cdot CaO(s) + Si(s) \longrightarrow 2\,Mg(g) + Ca_2SiO_4(s)$$

This reaction is highly endothermic ($\Delta H \approx 230$ kJ/mol Mg). The Mg vapor pressure reaches 0.1 MPa at 1470 °C. However, in industrial operations, Si is used in the form of an Si-rich ferrosilicon alloy. As the reaction progresses, the amount of Si in the alloy is reduced. Spent FeSi typically contains 20 wt % Si. An Mg pressure of 0.1 MPa is reached at ca. 1700 °C when dolime and 20 % FeSi are in equilibrium. If the dolime is mixed with other oxides, such as Al_2O_3 and SiO_2, to enhance formation of a liquid slag, the temperature required to reach an Mg vapor pressure of 0.1 MPa may increase further. Industrial processes operate at reduced pressures to allow operation at lower temperatures (1200 – 1600 °C), thus reducing the wear on construction materials and suppressing the formation of gaseous species other than Mg.

When aluminum is used as the sole reductant, magnesium spinel will be formed [86]:

$$4\,MgO(s) + 2\,Al(l) \longrightarrow 3\,Mg(g) + MgAl_2O_4(s)$$

Aluminum is a stronger but more costly reductant than silicon ($\Delta H \approx 165$ kJ/mol Mg). An Mg vapor pressure of 0.1 MPa can be achieved at a temperature of ca. 1360 °C.

Reduction is carried out in batch mode due to vacuum operation. Work has been aimed at developing atmospheric processes, allowing continuous operation and collection of magnesium in liquid form [84], [86], [87].

Three principles are applied for the industrially reaction chamber:

1) Externally heated retorts producing 70 kg/d (Pidgeon)
2) Internally heated reactors producing 2 t/d (Bolzano/Brasmag)
3) Internally heated reactors with molten slag producing ca. 12 t/d (Magnetherm)

Pidgeon Process [39–42], [88]. The process developed by PIDGEON in the early 1940s is presently used by Timminco in Canada, in two Indian plants, and in a large number of plants in China, with an estimated total capacity of the order of 170 000 t/a in 1999 (see Fig. 12). Briquettes of crushed calcined dolomite and ferrosilicon fines in a typical ratio of 5 : 1 are loaded into tubular refractory steel retorts, heated externally to a reaction temperature of 1200 °C, and evacuated to 10 – 25 Pa. Magnesium vapor is condensed at the water-cooled end of the retorts in the form of "crowns", which are subsequently removed for remelting and casting into ingots.

Reaction kinetics depend on the thermal conductivity of the briquettes, the shrinking core pattern of the reaction zone, and the diffusion rate of magnesium vapor. Heat transfer to the charge limits the diameter of the retorts. Typical retorts are 3 m long and have a bore diameter of 300 mm; each retort yields around 70 kg of magnesium per day. Normally, a slight excess of silicon above the stoichiometric requirement is used. Recovery increases with increasing ferrosilicon concentrations. Consumption figures per tonne of magnesium in Chinese plants have been reported as follows [88]: 0.9 MWh electric energy, 10.5 t coal, 11 t dolomite, 1.1 t of 75 %

ferrosilicon, with an 82 % overall magnesium recovery and 6.2 t of slag produced.

Starting from a high-purity dolomite raw material (99.5 % $CaCO_3 \cdot MgCO_3$) makes it possible to produce 99.95 % or better magnesium in commercial quantities. Attempts are being made to improve the process, e.g., to increase capacity by increasing the retort diameter [89].

Figure 12. Flow sheet for the production of metallothermic magnesium (Pidgeon and Bolzano processes)

Bolzano Process [43], [44]. The Bolzano process was formerly operated in Italy, but now only in Brazil by Brasmag. It employs an internally heated, brick-lined cylindrical reactor (Fig. 13). The briquetted charge of homogeneously mixed calcined dolomite and ferrosilicon fines (d) is loaded on a charge support system (e). Internal electrical heating (f) is conducted to the charge through the charge support system. The process operates at 1200 °C and < 400 Pa. Magnesium vapor condenses inside the condensers, which are water-cooled to 400 – 500 °C. Each reactor has a production capacity of ca. 2 t of magnesium per 20 – 24 h reaction cycle. Production of 1 t of magnesium consumes 7 – 7.3 MW·h, 5 – 5.2 t calcined dolomite, and 0.7 t of silicon contained in 78 % ferrosilicon, with 81 % silicon recovery; 5 – 5.2 t of slag is produced per tonne of magnesium and sold for use in plaster and building bricks. Mechanization of charge handling and slag removal is a challenge in this process. Magnesium with a purity of 99.98 – 99.99 % is obtained.

Figure 13. Bolzano reactor
a) Steel mantel; b) Refractory; c) Removable charge pack; d) Charge briquettes; e) Charge support; f) Electric heating connection; g) Removable condenser; h) Condensed magnesium

Magnetherm Process [46–48]. The Magnetherm process was developed by Pechiney Electrometallurgie in the early 1960s and has been used at the company's magnesium extraction plant in Marignac, France until 2001. The process is also operated by Magnohrom (Yugoslavia), and on a larger scale by North West Alloys (United States) until 2001. The total installed production capacity worldwide up to

2001 was 65 000 t/a. The overall equation for the process is

$$2\,MgO{\cdot}CaO\,(s) + Al_2O_3\,(s) + (Fe)\,Si\,(s) \longrightarrow Ca_2SiO_4{\cdot}Al_2O_3\,(l) + Fe\,(l) + Mg\,(g)$$

The dicalcium silicate slag formed in the reaction of calcined dolomite with ferrosilicon (Pidgeon and Bolzano processes) has a melting point of 2000 °C and is solid at the reaction temperature (1200 °C). The Magnetherm process, however, operates with a partly molten slag of the general composition $2\,CaO{\cdot}SiO_2{\cdot}nAl_2O_3$ at 1550 – 1700 °C. Typically, the slag may contain 55 % CaO, 25 % SiO_2, 14 % Al_2O_3, and 6 % MgO, some 40 % of which is in the form of solid Ca_2SiO_4. The slag is kept in an electrically heated, cylindrical, brick- and carbon-lined steel vessel (Fig. 14). The power input is conveyed through a water-cooled copper electrode (a) from the top through the slag (g) to the bottom graphite lining (b) of the reactor, which acts as a power outlet.

Coarse calcined dolomite and alumina screened to 3 – 30 mm, as well as ferrosilicon containing a minimum amount of fines, are added continuously to the slag under a vacuum of 3 – 6 kPa through charge holes in the water-cooled furnace roof. Magnesium vapor is condensed in a separate condenser system.

Calcined magnesite may be used as a supplement to the dolomite to adjust the slag composition. Calcined bauxite may be used alternatively to Al_2O_3. Aluminum metal may be used as a secondary reductant and Al source.

The main endothermic reaction takes place close to the surface of the slag. Deeper in the molten slag, the higher pressure slows down and finally stops the reaction at a silicon content in the bottom layer of ca. 20 %. Slag and 20 % ferrosilicon are tapped twice during a cycle of ca. 18 h, having produced more than 10 t of magnesium. Adjustment of the slag composition to higher magnesium oxide content and heating the surface of the slag with arc or plasma burners to 1900 – 1950 °C have been suggested to allow reduction to occur at atmospheric pressure [45], [90].

Production of 1 t of magnesium typically requires 4.6 t calcined dolomite, 0.6 t alumina, 0.85 t of 75 % ferrosilicon and 7 – 8 MW · h electric energy. About 5 t of slag is produced per tonne of magnesium and is used in the cement industry, for road building, and as a source of magnesium and silicon in agricultural soil. The ferrosilicon byproduct (yield 0.3 t per tonne of magnesium) is used in the metallurgical industry, in the production of heavy-liquid media for the separation of metals, or in drilling mud.

4.3. Refining and Casting

All magnesium extraction processes are followed by refining to remove impurities and casting to convert the metal to ingots, billets, slabs, or granules [5].

Refining.

Nonmetallic impurities in the form of particulate oxides, nitrides, carbides, and chloride inclusions impair corrosion resistance as well as mechanical and surface properties. Most alkali metal chloride and magnesium chloride fluxes wet and coat the surface of the impurity particles. The higher density of the chlorides causes the impurities to sink to the bottom of the melt as a sludge. Fluxes are composed to maintain a minimum difference in density of 0.15 – 0.20 g/cm^3 relative to that of the metal.

Inspissating (thickening) agents such as magnesium oxide and calcium fluoride reduce

Table 6. Composition of fluxes used in melting and refining (wt %)

Purpose	$CaCl_2$	NaCl	KCl	$MgCl_2$	CaF_2	MgO
Melting	40	30	20	10		
Melting and refining	20	10	10	35	15	10
Refining	15	10	10	35	20	10

the fluidity of the sludge to prevent it from contaminating the metal after settling. Inspissating fluxes are also used to protect the metal surface during holding and casting because of their viscosity and stability (Table 6).

Metallic impurities are normally controlled by the choice of raw materials and extraction process parameters. The most common metal impurities in pure magnesium are iron, copper, nickel, manganese, zinc, aluminum, silicon, calcium, and sodium. Intermetallic particles of aluminum, manganese, iron, and silicon have also been identified.

Heavy metals reduce the corrosion resistance of magnesium while acting as cathodes in galvanic cells in the metal. Metallic impurities are also undesirable for certain applications in which magnesium is used as a reductant (Ti, Zr, U) or as a canning material for the fuel elements in nuclear reactors where the metal's neutron absorption properties are important.

The solubility of iron in pure magnesium is 0.018 wt % at 650 °C, increasing with temperature to ca. 0.04 wt % at 750°C [107]. A content of 200 – 400 ppm Fe is thus typical for commercial-grade Mg. The principles for removing iron by means of manganese and aluminum, to give a considerably more corrosion resistant alloy, was discovered more than 70 years ago, but the industrial importance of this was not recognized until the 1980s. In aluminum-free alloys, zirconium may be used to remove iron.

Hydrogen present in magnesium is partly due to pick-up from the moisture in air and in flue gas from gas or oil burners. $MgCl_2$ and other salt components are strongly hygroscopic and easily pick up water. Magnesium has a much higher solubility for hydrogen than aluminum, and typical contents in Mg and Mg alloys are 2 – 12 mg/kg. While inert gas purging removes hydrogen in molten Al or AlMg alloys fairly readily, this is not the case in molten Mg due to the unfavorable thermodynamics [108]. Due to the high vapor pressure of Mg, it is hardly an alternative to remove hydrogen by means of vacuum extraction. However, hydrogen in magnesium die cast parts is normally not considered a problem, as possible hydrogen porosity only adds to the porosity usually present anyway. For gravity cast magnesium alloys, hydrogen may be problematic, as for magnesium used as an alloying element in aluminum.

Equipment. The standard equipment in magnesium refineries consists of large, stationary, brick-lined furnaces or externally heated steel crucibles containing 10 – 25 t or 2 – 6 t of molten magnesium, respectively. The stationary furnaces can be heated electrically, with gas or oil burners from the top or side, or by submerged electrical heating systems.

Electrolytic magnesium recovered and processed in the molten state can be refined in continuous stationary furnaces with metal yields greater than 99.5 % and negligible flux consumption (Fig. 15) [49], [106].

Metallothermic magnesium crowns or condensates are recovered in the solid state. Standard practice involves batchwise melting and refining in steel crucibles and subsequent transfer to casting furnaces. The melting process and the high content of nonmetallic impurities require a flux consumption that is 5 – 10 % of the metal volume; metal recoveries are in the range 95 – 98 %.

Casting. Highly automated casting by pumping or static pressure is state of the art. Magnesium contracts by 4 % during solidification and 5 % during cooling to 20 °C, and hence is sensitive to surface cracks and shrink holes. Turbulent flow favors the formation of nonmetallic inclusions. Consequently, care is taken to control the solidification process and to reduce turbulence. At elevated temperature or in the case of turbulent metal flow, sulfur powder may be sprayed on the metal surface to sup-

Figure 15. Norsk Hydro refining furnace [49]
a) Salt melt; b) Magnesium metal; c) Electrodes; d) Refractory; e) Sludge; f) Tapping spout; g) Partition wall; h) Metal port; i) Refractory cover

press oxidation by creating an SO_2-containing atmosphere.

The level of impurities in standard 99.8 % magnesium does not influence the solidification pattern. Pure magnesium solidifies at its melting point (650 °C). During holding and casting, the metal surface is protected against oxidation by a protective gas. Acting together with oxygen in the air, low concentrations of sulfur hexafluoride or sulfur dioxide in air form protective layers on the metal surface. Sulfur hexafluoride has been widely used during the last twenty years [50], [51], but due to the high global warming potential of SF_6 (GWP factor: 23 900), SO_2 is gradually being reintroduced [109]. Due to the negative impact of SO_2 on the working environment, efforts are made to find alternatives [110].

Pure magnesium rounds and T-bars and alloy billets are cast in multistrand continuous or semicontinuous direct-chill casting machines, also using state of the art hot-top and airslip technologies. The main safety concern to be managed by these technologies is associated with metal – water contact, which could result in hydrogen evolution and potential explosions.

To avoid discoloration and surface corrosion during transportation and handling, the metal is protected by suitable wrappings. The state of the art is to use dissicants inside the containers during transport in severe climatic conditions.

Recycling. Recyclability is important for the economic application of magnesium, especially for the rapidly growing application of die-cast parts made from magnesium alloys, e.g., in the automotive and electronics industries.

In typical magnesium die-casting operations, only around 50 – 70 % of the purchased ingot is present in finished castings, the remainder being production scrap of various qualities. The majority of the scrap (85 – 95 %) is normally sorted into so-called Class 1 scrap, suitable for remelting operations. Such clean scrap can be recovered to primary-metal quality [111]. The remelting requires less than 5 % of the energy required to produce primary metal.

Two principally different methods for treatment of scrap may be utilized [114]:

1) Flux-based metal protection and refining
2) Protective gas (SO_2/SF_6) for melt protection and settling, possibly assisted by argon purging or filtration (flux-free refining)

Flux-based protection and refining has been most widely used, and is probably still the most important in terms of tonnage. Recycling of magnesium by using salt fluxes has a potential to improve the recovery, but disadvantages are that the salt flux is corrosive to the surrounding equipment and environment (HCl fumes), and that it generates a sludge in the lower section of the crucible. It also creates a possibility of having salt inclusions in the cast product, and flux-free melting is thus preferred by die casters who recycle in house [115]. Chlorides may also combine with organic residues on the scrap to form highly toxic compounds, creating a need for comprehensive off-gas treatment systems.

The increasing use of recycling has generated an interest in metal cleanliness and various methods for determining the inclusion content have been developed [112].

Magnesium alloys from scrapped automobiles (end-of-life vehicles) as well as other post consumer scrap represent an increasing volume, and will be a technological challenge to the industry in the future.

4.4. Particulate Magnesium

Particulate magnesium comprises powders, granules, turnings, and raspings; particle sizes range from 0.04 to 5 mm, and particle shapes vary. Particulate products are used in chemical and metallurgical processes in which magnesium acts as a reagent, catalyst, or alloying element. Fine powders are used in pyrotechnics.

Particulate magnesium is considered inflammable and subject to specific labeling and packing regulations according to IMDG codes classes 4.1 and 4.3; UN No. 1869 and 1418; CFR 49: 172.01, flammable solid; RID/ADR class 4.1, number 13 b, class 4.3 number 1 d.

Flowability, uniformity of grain size, and defined area – volume ratios are important for injection into molten metal (steel, aluminum). Particulate magnesium is frequently blended with inert and active components (e.g., lime or alumina) or coated with salt or refractories. These products are used for desulfurization of iron. Blending and coating reduce the reactivity and increase the magnesium yield. Turnings and raspings commonly used for Grignard syntheses and pharmaceuticals are adjusted for reactivity (surface-to-weight ratio) and form of the particles according to customer specifications. Finely divided powder for pyrotechnics is subject to narrow tolerance limits, including the content of organic material.

Particulate magnesium is produced directly from the molten state by shotting, atomization, or granulation or by machining ingots, slabs, or billets, with subsequent grinding and screening. Airborne dust with a particle size below 0.15 mm is explosive. Safety precautions for machining and atomizing operations include prevention of explosion hazards in the processing and handling of fine dust, as well as design of the general plant layout to limit the consequences of accidental blowouts. Clean operation and personal hygiene are important.

Nearly spherical magnesium shots in the 0.2 – 2-mm size range are produced by nozzle spraying in a cooling tower with an inert atmosphere [52]. Atomizing is performed in a protective atmosphere of argon, helium, or methane. Magnesium may be atomized on a rotating disk or in a gas stream. During shotting and atomizing, precautions are taken to avoid the formation of layers of highly ignitable, pyrophoric substances.

Salt-coated granules were originally developed in the Soviet Union and are produced by mixing alkalimetal chloride salts and molten magnesium in a rotating perforated cup; the metal is disintegrated by centrifugal force with subsequent air cooling. Spheroidal particle sizes range from 0.2 to 2.5 mm, with a salt content of 10 % [23], [53]. Other methods include mixing molten mixtures of magnesium and alkalimetal chlorides and adding a stabilizing boron compound [54]. Various proprietary processes employ eutectic salt compounds with low hygroscopicity to produce particles with high flowability [55]. The salt and metal are separated by gentle crushing and screening, leaving granules with 5 – 10 % salt as coating. The production of salt-coated granules is safer than that of pure magnesium powder and can be integrated in normal foundry operations.

5. Environmental Aspects

Magnesium production processes require installations for cleaning off-gases, and most of them also for treatment of wastewater. Significant amounts of solid waste are deposited as landfill but may in some cases be used for agricultural purposes due to their content of magnesium or potassium. In production processes involving calcination of carbonate minerals or dehydration of hydroxides, dust is removed by conventional methods. The main emissions to air are carbon dioxide, nitrogen oxides, and sulfur dioxide from the combustion and calcination processes.

In *electrolytic processes*, carbon is used in some cases as a reductant in the preparation of anhydrous magnesium chloride, and carbon is always used as anode material in electrolysis. The presence of carbon, water, chlorine, or hydrogen chloride, even in low concentrations, at elevated temperature leads to formation of chlorinated

hydrocarbons and other organic compounds. Chloromethanes, chlorobenzenes, polychlorinated biphenyls (PCBs), chlorodibenzofurans, and chlorodibenzo-*p*-dioxins are highly toxic and are only slowly degraded in nature. Although such compounds only occur in liquid effluents from scrubber systems at low concentrations (a few micrograms per liter), collection and destruction are of great environmental importance.

Chlorinated organic compounds can be either in solution or present as small particles in the liquid effluents. Particles may be flocculated with appropriate cationic or nonionic agents. The agglomerates adhere to solid inorganic particles that are often present in the effluents (carbon and hydroxides or oxides of iron, aluminum, silicon, etc.). The particles are removed by filtration or centrifugation. Liquids may be treated with activated carbon.

Traces of chlorine and hydrochloric acid in off-gases are scrubbed, recycled, or neutralized by conventional methods. Where available, sea water is an efficient medium for scrubbing of acidic components such as chlorine, hydrogen chloride, and sulfur dioxide. Off-gases containing chlorinated hydrocarbons may be subjected to incineration or activated carbon treatment.

Solid byproducts from *metallothermic processes* are either used for industrial purposes or deposited as landfill.

Sludge from *foundry operations* contains entrapped metallic magnesium globules. When deposited as landfill, precautions must be taken to control the formation of hydrogen gas by the reaction of entrapped magnesium with water. Off-gases from foundry operations containing hydrogen chloride, sulfur dioxide, and magnesium oxide may be scrubbed by conventional methods to comply with local regulations.

6. Quality Specifications

Standard designations for unalloyed magnesium in the form of ingot or stick for remelting are listed in Tables 7 and 8. These figures correspond to ISO 8287 (2000-04-01), ASTM B92 (re-approved 1994) and EN 12421 (1998). Grade 9980 (99.80) is adequate for most uses and can be obtained by electrolysis by using controlled standard operations. Grades 9995 (99.95) and 9998 (99.98) are normally produced only by metallothermic processes. High-purity magnesium can also be produced by distillation of lower grades, but this is expensive [5], [23].

Figure 16. Consumption of magnesium by application

7. Uses

The uses and consumption of magnesium are summarized in Figure 16. The overall growth rate in the use of magnesium is estimated to be 3 – 5 % per annum.

Aluminum Alloys. The largest single use of magnesium is as an alloying element in aluminum alloys (→ Aluminum Alloys), which can contain 0.5 – 4.5 % Mg. Aluminum – magnesium alloys have improved ductility, enhanced resistance to saltwater corrosion, and improved cryogenic properties. User forms are ingots weighing 1 – 25 kg and sows and T-bars weighing 250 – 500 kg. The market growth of this application depends on the growth of aluminum and the recycling efficiency of aluminum scrap, particularly beverage cans.

Desulfurization and Nodularization. Magnesium is used as a hot-metal desulfurizing agent for the production of high-quality steels. Due to development of powder-injection technology, it is now possible to inject solid Mg-based reagents containing 50 – 80 % magnesium deep into a liquid iron bath, to produce steels with a sulfur content as low as 0.002 % [56], [57]. The magnesium consumption in the desulfurization process depends mainly on the sulfur to be removed, and is typically 0.5 kg of Mg per tonne of metal.

Magnesium is also used in the production of ductile iron, also known as nodular cast iron. Ordinary cast iron is very brittle at room temperature because it contains carbon in the form of flakes or laminar graphite. Addition of magnesium to liquid cast iron, either as pure solid magnesium or alloyed with ferrosilicon, modifies the laminar graphite into nodular graphite (globules), thereby inducing ductility (elongation in the range of 14 – 18 %), and making it suitable for several other industrial applications [91], [92].

Magnesium-based alloys represent the fastest growing area of magnesium application (see Fig. 16). They are normally delivered as alloyed ingots from the primary producers (→ Magnesium Alloys). According to the International Magnesium Association, over 90 % of shipments of magnesium alloys are consumed in the manufacture of high-pressure die castings, particularly for automotive applications; automotive die-castings make up 85 – 90 % of the total annual weight of die castings produced. Limits on fuel consumption and vehicle emissions imposed by CAFE (USA) and plans for such legislation in the EU have promoted the increasing use of magnesium in automobile production to reduce vehicle weight. Other growing applications include consumer electronics such as laptop computers, cell phones, and cameras, where magnesium's light weight, damping ca-

pacity, recyclability, and relative strength give it a clear advantage over alternative materials.

Chemical applications include the use of magnesium as a reagent in the production of titanium and zirconium by the Kroll process (→ Titanium, Titanium Alloys, and Titanium Compounds), the reduction of uranium fluoride to uranium metal, and the production of beryllium and hafnium. Titanium constitutes by far the largest user segment in this group, the magnesium being added in ingot form. Magnesium chloride from the Kroll process is electrolyzed to recover magnesium and chlorine. The normal magnesium requirement to compensate for losses is 0.1 t per tonne of titanium.

Magnesium raspings for the production of metallic uranium have a specified limited content of boron, cadmium, and rare-earth elements including gadolinium, samarium, europium, and dysprosium.

The use of particulate magnesium, raspings, or turnings in Grignard syntheses has been declining, due primarily to restricted use of tetraethyl lead.

Hydrogen Storage. Magnesium forms the hydride MgH_2, which is stable at room temperature (→ Hydrides, Chap. 2.6.). A hydrogen equilibrium pressure of 0.1 MPa is reached at ca. 290 °C [93]. At 25 °C the hydrogen pressure is less than 0.1 Pa. MgH_2 contains 7.66 wt % hydrogen and about 1.5 times more hydrogen than liquid hydrogen for a given volume. MgH_2 is therefore an interesting candidate as a hydrogen carrier, e.g., in onboard storage tanks for hydrogen for vehicles driven by fuel cells or hydrogen-combustion engines.

The reversibility of hydrogen absorption/desorption is poor for normal Mg powders, but improves greatly when the particle size is well below 1 μm and catalysts are added [94]. Of the theoretical amount of hydrogen 80 % (6 wt %) can be reversibly absorbed and desorbed at 300 °C within 10 min by using nanocrystalline Mg particles and various catalysts such as Pd and Fe [94].

Also Mg–Ni alloys close in composition to the compound Mg_2Ni can store significant amounts of hydrogen (3.6 wt %). The benefits of Mg_2Ni compared to pure Mg is that the temperature of absorption/desorption can be lowered from about 300 °C to about 200 °C [95].

Other Uses. The electronegative character of magnesium is used for corrosion abatement as sacrificial soil and hot-water-tank anodes. European restrictions on aluminum in drinking water have encouraged the use of magnesium anodes for hot-water tanks. Magnesium batteries for military purposes and rescue systems combine light weight and high energy content.

8. Economic Aspects

Since 1990 the use of magnesium has grown at a rate of 3–5 % per year, and this is expected to continue at a similar rate. The main reason for this forecast growth is the increasing use of magnesium in die-casting applications (a rise of 15 % per year is forecast over the next decade), particularly for use in the automotive industry. The main consumer regions in 2000 were North America (176.7×10^3 t), Western Europe (122.9×10^3 t), and the Pacific Rim (50.5×10^3 t), with the rest of the world (including China and the former Soviet states) consuming around 50×10^3 t. The optimistic predictions for growth have encouraged the development of a number of projects for new magnesium production facilities in, amongst others, Australia, the Netherlands, and the Republic of Congo. However, in 2001, in the face of increasing competition from Chinese production, three major producers, Pechiney in France, Northwest Alloys in the USA, and Norsk Hydro in Norway, were forced to stop primary production. Production capacities of main producers as of 2001are given in Table 9.

Several plants were closed also in the 1990s: the Dow Chemical plant closed in December 1998, and there were closures in Italy and Japan in the early 1990s. Production in the former Soviet Union has decreased in recent years, due to changes in titanium requirements. In contrast, China is now a major producer. Total world production of magnesium in 2000 was 405×10^3 t (see Table 10), and consumption was 400×10^3 t. Magnesium production is now divided fairly equally between the electrolytic and thermic processes.

Table 9. Main magnesium producers (2001)

Company	Installed production capacity, 10^3 t	Production process	Comments
Northwest Alloys, USA	45	thermic	Closed in October 2001
Norsk Hydro Canada, Inc.	45	electrolytic	Expanded to 48 in 2002
MagCorp, USA	43	electrolytic	
Norsk Hydro ASA, Norway	42	electrolytic	Closed primary prod. in March 2002
Dead Sea Magnesium, Israel	33	electrolytic	
Pechiney Electromet., France	20	thermic	Stopped prod. in 2nd quarter 2001
Timminco Metals, Canada	6	thermic	
Magnola Metallurgy, Canada	63	electrolytic	First commercial prod. in 2001
Brasmag, Brazil	10	thermic	
Magnohrom, Yugoslavia	5	thermic	
Avisma, Russia	25	electrolytic	
Ust-Kamenogorsk, Kazakhstan	20	electroytic	
Solikamsk, Russia	18	electrolytic	
Oriana, Ukraine	15	electrolytic	
China	170	thermic	Estimated capacity
	10	electrolytic	

The evolution of world production of primary magnesium from 1980 to 2000 is summarized in Table 10. Up to 1998 the United States was the largest producer (ca. 40 % of the world total), followed by China (20 %) and Canada (16 %). However, the picture changed somewhat with the closure of the Dow plant, and China is now by far the largest producer country. Most of the growth in the last decade has been in China, where a large number of plants of varying capacity using the Pidgeon process have started up.

Table 10. Evolution of world primary magnesium production (10^3 t/a)∗

Country	1980	1990	2000
Brazil		6.5	9
Canada	9.3	26.7	55
China	7	5.8	140∗∗
France	9.3	14.6	15
Italy	9.7	5.7	
Israel			33
Japan	9.3	12.8	
Norway	44.4	48.2	42
Poland	0.5		
Soviet Union/CIS total	76	88	45∗∗
United States	154.1	139.3	65∗∗
Yugoslavia	0.5	5.8	1
World total	320.1	353.5	405

∗ Data from the U.S. Geological Survey and the International Magnesium Association. ∗∗ Estimated.

There is no organised terminal market for magnesium; the major producers control their own distribution network. Prices (see Fig. 17), having risen to a high of over 230 c/lb at the end of 1995, have since dropped sharply, due in large part to downward pressure from Chinese producers.

Figure 17. Price development for pure magnesium; Average year end US Spot Western Price in nominal terms (Source: Platts Metals Week)

The U.S. standard import duty on pure magnesium is 8 %. In addition there is an 305.56 % antidumping tariff on imports of Chinese pure magnesium into the States (one specific exporter has a lower tariff of 24.67 %). The European Union raised its antidumping duty on imports

of Chinese pure magnesium to 63.4 % in 2000; however, this duty will probably be dropped when Pechiney, the only EU producer of magnesium, announces the final closure of its plant in France.

9. Toxicology and Occupational Health

Magnesium is an essential element for human, animal, and plant life, and the toxicity of the metal is regarded as low. The toxicity of magnesium compounds is usually attributed to the anion [96]. Judging from the literature, the focus with respect to magnesium is on the effects of Mg deficiencies rather than the toxic properties of the metal. RTECS has no entries on magnesium, and no reports of serious poisoning of workers in industry have appeared in the literature. There is no evidence of lung injury as a result of Mg dust inhalation. Inhalation of freshly generated magnesium oxide, however, did experimentally induce metal fume fever in humans, but with a considerably milder response compared to that due to zinc oxide. No reports of industrial experience of this appear to have been made [96], [97]. Some investigators have reported a higher incidence of digestive disorders in magnesium plant workers and have suggested that a relationship may exist between magnesium absorption and gastroduodenal ulcers. Slivers of magnesium penetrating the skin or entering deep wounds can cause "aeroform tumours" or "gas gangrene", but reported cases have in no way paralleled those seen in animal experiments. Magnesium powder may cause irritation to the skin, mucous membranes, and upper respiratory tract [98].

Symptoms such as subjective feeling of heat and immense thirst, blurred vision, nausea and vomiting, CNS depression, hyporeflexia, hypothermia, hypotension, bradycardia (depressed pulse rate), respiratory depression, and even respiratory and cardiac arrests have been reported in connection with hypermagnesemia as a result of massive intakes of laxatives and antacids (i.e., magnesium sulfate and magnesium hydroxide) and inadvertently administered overdoses of magnesium compounds during medical treatment [99].

Humans are exposed to magnesium during the production, casting and machining of the metal and through dietary intake. The most serious hazard presented by magnesium is the danger of burns from molten metal.

10. Safety

Magnesium is for most end users a safe metal. Magnesium has a very high affinity for oxygen, and a magnesium oxide film is quickly formed on any freshly cut surface. This film prevents further oxidation of the metal. Ready-made magnesium parts, e.g., in the automotive industry, represent no hazard to the user.

There are some processes during production, manufacturing, and recycling of magnesium where special safety precautions must be taken. Molten magnesium will burn if exposed to air. Cover gases and fluxes are used during casting in magnesium foundries to prevent liquid magnesium from reacting with oxygen. A magnesium dust atmosphere may burn and explode if an ignition source is present [100]. Dust atmospheres are rare, but may be encountered during accidental events in foundries or recycling plants or during firefighting. Small magnesium chips will burn if ignited. They may release hydrogen if brought in contact with water, producing a potentially reactive atmosphere.

Special care must be taken in extinguishing magnesium fires. Recommendations are given in the National Fire Protection Association (NFPA) publications [101], [102]. Water is usually the wrong agent for magnesium fires because the metal reacts with water to form hydrogen, which will contribute to the fire. Furthermore, violent steam explosions can result if water enters molten metal. As an exception, where only small quantities of magnesium are involved, the fire may be extinguished by applying large amounts of water, provided no pools of molten magnesium are present. For larger fires, dry (water-free) extinguishing agents should be used, e.g. dry salt (sodium chloride) or magnesium foundry fluxes (mixed alkali and alkaline earth metal chlorides and fluorides).

Helium and argon are inert to magnesium and can be used to smother a magnesium fire. However, nitrogen, carbon dioxide, and halons are not inert, and will react with molten magnesium.

1. Introduction

Most primary magnesium is used for metallurgical purposes: in alloying additions to aluminum and other metals, in magnesium-based alloy castings and wrought products, for desulfurization of iron and steel, for nodularization of ductile iron, as a reducing agent to produce metals from their oxides and chlorides, and in anodes for cathodic protection. Chemical uses include the production of magnesium compounds and as a catalyst in Grignard reactions. Its low density (ca. 1.8 kg/dm^3 in alloy form), coupled with favorable casting properties, makes magnesium the material of choice for lightweight components. Magnesium-based alloy castings and wrought products make up about 37 % of free-market magnesium shipments.

Information on the properties, production, fabrication, and use of magnesium alloys can be found in [4–9], [28–32]. A compilation of alloy properties and product design information is given in [2], [28], [30], [32]. Commercial magnesium alloy products are described in [3], [33], [34].

2. Commercial Alloys, Product Forms, and Uses

Designations for cast and wrought magnesium alloys, in accordance with ASTM B 275 [3], are based on their chemical composition. Letters represent the principal alloying elements:

A	aluminum	M	manganese
C	copper	Q	silver
E	rare earth metals (RE)	S	silicon
G	magnesium	T	tin
H	thorium	W	yttrium
K	zirconium	Z	zinc
L	lithium		

These are followed by respective weight percentages rounded to whole numbers and a serial letter that differentiates slight variations in compositions. Temper designations are in accordance with ASTM B 296 [3]:

F	as fabricated
O	annealed, recrystallized (wrought products only)

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a15_581

H	strain hardened
	H1 strain hardened only
	H2 strain hardened and then partially annealed
	H3 strain hardened and then stabilized
T	thermally treated to produce stable tempers other than F, O, or H
	T4 solution heat treated
	T5 cooled and artificially aged
	T6 solution heat treated and artificially aged
	T7 solution heat treated and stabilized
	T8 solution heat treated, cold worked, and artificially aged

The compositions of a range of casting and wrought alloys are listed in Table 1. Alloys for die casting contain very small amounts of the heavy-metal impurities nickel, iron, and copper [3], [33], [34].

Table 3. Characteristics and typical uses of some magnesium alloys

Alloy	Characteristics and uses
Cast Alloys	
AM50A/AM60B	high-pressure die-casting alloy with outstanding ductility in the -F condition; used for automobile parts
AS41A/B	die-casting alloy with good creep properties up to 150 °C; used for automobile parts
AZ81A, AZ91C/E, ZE41A	general-purpose sand and permanent mold-casting alloy used for aircraft parts, machinery components, gearboxes
AZ91B/D	general-purpose die-casting alloy for automobile and computer parts, chain saws, sporting goods, cameras, projectors, and household equipment and appliances
EZ33A	high-temperature alloy for sand and permanent mold casting; excellent castability; creep resistant up to 250 °C and pressure-tight; used in aerospace and military applications
Wrought Alloys	
AZ31B/C	moderate strength general-purpose alloy used for luggage, ladders, hand trucks, bakery racks, and concrete tools
AZ61A, AZ80A, ZK60A	higher strength alloys used in batteries, military components, shelters, tent poles, and tennis racquets
HK31A	elevated-temperature alloy used in aerospace and military applications

Typical mechanical properties of cast and wrought alloys are listed in Table 2. The physical properties of magnesium alloys are in the following range (RT = room temperature):

Density (RT)	1.7 – 1.8 g/cm^3
Electrical resistivity (RT)	50 – 170 nΩ·m
Heat of fusion	280 – 373 kJ/kg
Melting range	445 – 650 °C
Specific heat (RT)	960 – 1050 J kg^{-1} K^{-1}
Linear coefficient of thermal expansion (RT)	$(26.5-27.3)\times 10^{-6}$ K^{-1}
Elastic modulus (RT)	45 GPa

A general description of alloy characteristics and typical uses is presented in Table 3. Equivalent alloy designations used in industrialized countries are given in [33], [34], [50].

3. Metallurgy of Magnesium Alloys

[1], [2]

Magnesium in its pure form is soft, mechanically weak, and hence not generally used for structural applications. By careful selection of alloying elements, both general-purpose alloys and alloys for special applications can be produced. As with other metallic alloy systems, a combination of well-known hardening mechanisms (solid solution hardening, particle dispersion hardening, work hardening, and grain boundary hardening; → High-Temperature Materials, Chap. 3.) determines the mechanical properties of magnesium alloys. Alloying additions influence other properties including reactivity of the melt, castability, and corrosion performance.

The alloying elements used with magnesium can be grouped into two categories :

1) Elements that actively influence the melt include beryllium (≤ 30 ppm), which lowers the rate of melt oxidation, and manganese (≤ 0.6 wt %), which reduces the iron content and hence the corrosion rate of the alloys. These additions are active in relatively small amounts and do not require extensive solubility in the melt.
2) Elements that modify the microstructure of the alloy by via the above-mentioned hardening mechanisms include those that influence castability. Except for grain-refining additions (carbon inoculation), which can be active in small amounts, these elements must be relatively soluble in liquid magnesium. Commercially interesting alloying elements include aluminum, cerium, copper, lanthanum, lithium, manganese, neodymium, silver, yttrium, zinc, and zirconium.

3.1. Magnesium – Aluminum Alloys

Aluminum is by far the most important alloying element for magnesium. Its maximum solid solubility in the Mg – Al system is 12.7 wt % at the eutectic temperature of 437 °C (Fig. 1). The eutectic contains 32 wt % aluminum, and it consists of α-Mg and $Mg_{17}Al_{12}$. Commercial alloys contain less than 10 wt % aluminum and, according to the equilibrium diagram, should solidify into a homogeneous matrix of magnesium with aluminum in solid solution. This is, however, not the case – a relatively large volume fraction of eutectic constituents is formed (Fig. 2). The solidification diagram shows a distinct plateau at the eutectic temperature (Fig. 3).

Scheil's equation describes freezing under nonequilibrium conditions where solute diffusion is negligible, so that a strongly segregated material results. The fraction solidified as a function of temperature for equilibrium and nonequilibrium freezing is illustrated in Figure 4 for two Mg – Al alloys. In practice, the Scheil equation

Figure 1. Phase diagram for the binary system Mg – Al

Figure 2. Microstructure of low-pressure die-cast AM100 alloy (× 200)

Figure 3. Solidification diagram showing the temperature variation during cooling of the Mg – Al alloy AM 100 A
a) Temperature; b) Rate of temperature change

Figure 4. Fraction solidified as a function of temperature, calculated for equilibrium and nonequilibrium conditions for two Mg – Al alloys

provides a reasonable description of solidification during commercial casting processes.

The Mg – Al equilibrium diagram is typical of an age-hardenable system. After solution heat treatment at temperatures just below the eutectic temperature, the β-$Mg_{17}Al_{12}$ phase dissolves, and subsequent quenching gives a supersaturated solid solution. During artificial aging at 150 – 220 °C, a platelike precipitate forms and results in a significant hardening effect. A certain quench sensitivity is caused by a competing reaction, whereby the β-phase precipitates discontinuously along grain boundaries. This process occurs during cooling after casting or following solution heat treatment.

Commercial Mg – Al alloys usually contain a small amount of zinc (0 – 2 wt %), which strengthens them somewhat. Higher zinc contents increase the amount of eutectic constituents, lower the solidification temperature, and may cause hot shortness (cracking). Solution treatment of Mg – Al – Zn alloys increases their ductility. In the absence of solution heat treatment (as with high-pressure die-cast products), maximum ductility is obtained by using alloys of low aluminum and zinc content (e.g., AM60 alloy containing 6 wt % aluminum). Further improvement of ductility is possible with even less aluminum, but castability suffers somewhat.

High-temperature applications require improved creep properties, which are achieved by decreasing the aluminum content and thus the volume fraction of the low-melting eutectic. Fur-

ther improvements are possible by introducing elements that form finely dispersed particles in the matrix (dispersion hardening). In high-pressure die-cast parts that solidify rapidly, silicon addition causes the formation of finely dispersed MgSi particles; this is the basis of Mg – Al – Si alloys. Additions of rare earth elements and calcium have a similar effect on the microstructure and creep properties.

Manganese addition plays a crucial role in controlling the iron content by reducing the solubility of iron in the melt. Several high-purity alloys with greatly improved corrosion resistance are available commercially. Grain refining, when necessary, is performed by introducing carbon into the melt at > 750 °C (preferably ca. 780 °C).

3.2. Grain-Refined Magnesium – Zirconium Alloys

A series of high-performance magnesium-base alloys was developed after discovery of the extremely efficient grain-refining action of zirconium. This effect results from formation of a high density of tiny zirconium particles in the melt, which act as potent grain nuclei. An example of a zirconium-refined grain structure is shown in Figure 5. Unfortunately, elements such as aluminum and manganese lower the solubility of zirconium in the melt, thus precluding exploitation of this grain-refining mechanism in common aluminum-containing alloys.

Figure 5. Structure of a zirconium grain-refined alloy RZ5 (× 50)

Mg – Zn – RE – Zr. Binary Mg – Zn alloys show inferior mechanical properties and castability, but the addition of zirconium for grain refinement and rare earth (RE) elements to reduce microporosity led to the development of alloys such as EZ33 and ZE41. These alloys have been used widely as sand castings in the T5 condition (cooled and artificially aged) for applications involving exposure to moderately elevated temperature (up to ca. 200 °C). The ZE63 alloy is a high-strength variant in which solution heat treatment in a hydrogen atmosphere is employed to remove some of the embrittling Mg – Zn – RE grain boundary phases. In extrusion, microporosity is of less concern and Mg – Zn – Zr alloys are used without RE additions.

Mg – Ag – RE – Zr. Addition of silver and neodymium-rich mischmetal, in addition to zirconium, promotes age hardening efficiently when the alloy is given a full T6 treatment (solution heat-treated and artificially aged). The precipitates formed are relatively stable; the alloy shows high mechanical strength and good creep properties at temperatures approaching 250 °C.

Mg – Y – RE – Zr. This alloy system for high-temperature application is based upon additions of yttrium and neodymium-rich misch metal. This alloy system was developed to meet the ever-increasing high-temperature performance requirements of the aerospace industry and may replace the Mg – Ag – RE – Zr and thorium-containing alloys. The alloys must be melted in a special inert atmosphere (argon) and develop their properties by T6 heat treatment.

3.3. New Developments [11], [29], [31]

Conventional alloy development has reached a level at which most of the foreseeable potential has been exploited. Alloy modifications and the development of new alloys for die casting are mainly linked to high-temperature applications. Further improvements are possible by combining existing alloys or modified alloys with new processing routes. Squeeze casting and semisolid alloys are examples of active fields of research. Microstructural refinement through rapid solidification offers great potential for improving the properties of both conventional al-

loys and new alloy compositions. The ability of magnesium alloys to wet a number of reinforcing fibers and particulates efficiently makes the material attractive as a matrix in metal-based composites.

4. Production Methods for Magnesium Alloys

Alloying and Grain Refining. The most commonly used magnesium alloys contain aluminum, zinc, and manganese; aluminum and zinc are added in ingot form, dissolving readily at normal melt temperature (ca. 700 °C). Manganese is added as the anhydrous chloride or as a hardener, for example, Al – 5 % Mn. The alloying elements are added at 720 – 750 °C; the alloy is homogenized and then cast.

High-purity magnesium alloys such as AZ91D, AZ91E, AM60B, and AM50A contain very low contents of the heavy-metal impurities nickel, iron, and copper, and hence have far better corrosion resistance than ordinary alloys. Iron is removed by saturating the melt with manganese at elevated temperature (700 – 750 °C) and then loweringthe temperature, thus precipitating the iron in the form of an AlMnFe intermetallic compound.

Mechanical properties of magnesium alloys improve as grain size is reduced. Carbon inoculation is used commonly to grain-refine aluminum-containing magnesium alloys, the inoculant being added at ca. 780 °C. Zirconium is frequently used to grain-refine alloys lacking aluminum. It is added as a Mg – 30 % Zr hardener above 750 °C. The mechanisms of grain refining are not fully understood, but several theories have been proposed. Both zirconium and magnesium have hexagonal crystal structures with similar lattice parameters, making zirconium an ideal nucleating particle for magnesium.

Casting of Billets and Slabs. Fabrication of wrought magnesium products starts with the production of extrusion billets, forging billets, and rolling slabs, which are usually cast by continuous or semicontinuous direct-chill cast processes. The methods are similar to those used for alloys of other metals such as aluminum (→ Aluminum Alloys, Chap. 3.2.) and copper. Multistrand casting with downspout tubes and floats has proved difficult for magnesium.

Shaped Casting. Magnesium alloys can be cast by all known processes, including die and sand casting. Remelting and recycling of magnesium alloys are economically viable.

High-Pressure Die Casting. Two methods are used for high-pressure die casting: the molten metal is injected at high velocity into a reusable metal mold (die) in cold-chamber (as for aluminum) or hot-chamber (as for zinc) machines. Because of their lower specific heat (i.e., heat content) and thus faster solidification, production rates of magnesium high-pressure die castings are usually 30 – 40 % faster than those of aluminum alloys. In hot chamber machines the production rates for medium to large components are similar to those for zinc. Parts weighing up to 20 kg are cast in 50- to 5000-t locking capacity cold-chamber machines at a rate of 20 – 60 shots per hour. For smaller and thin-walled parts, hot chamber machines of 50- to 1000-t capacity are common, with production rates up to 400 shots per hour. Molten magnesium alloy is automatically metered and transferred in closed systems [12], [35].

Because magnesium does not attack steel to the same degree as aluminum, dies used for casting magnesium have lifetimes up to several times longer than those for aluminum. Draft angles for magnesium are lower than for aluminum, allowing casting of holes within tolerance limits.

Low-Pressure Casting. Low-pressure casting of magnesium has been performed successfully [13]. Typical production rates of 12 – 15 shots per hour are achieved when casting a 12-kg part in steel dies. The process is also applicable to casting in sand molds. The properties of the castings can be improved by heat treatment, making this method useful for a wide range of applications.

Sand Casting. In sand casting, molds are formed by ramming conventional naturally bonded molding sand around a pattern. Chemical inhibitors such as inorganic fluorides or boric acid are added to the sand to suppress the tendency for molten magnesium to react with moisture. Sometimes dry sand molds or skin-dried green sand molds (i.e., surface-dried by torching) are used to reduce the oxidation tendency

further. The advent of chemically bonded dry silica sand has allowed closer tolerances and the production of more complex castings.

Melt Protection [46], [47]. Due to magnesium's high affinity for oxygen and high vapor pressure, the molten metal will oxidize and burn in air. This problem can be solved by using salt fluxes and/or protective gases mixed with the atmosphere above the melt. However, salt fluxes tend to lower the corrosion resistance due to salt contamination, and therefore gas protection is currently used by most die-casters. Various gases can protect magnesium from oxidation. The most commonly used gas for melt protection is sulfur hexafluoride SF_6. In die-casting operations a concentration of 0.2 % in dry air (sometimes mixed with CO_2) is used. SF_6 has recently been identified as a strong greenhouse gas and should therefore be replaced. A substitute is sulfur dioxide, which was used by the magnesium industry in the past. Although SO_2 is toxic at higher concentrations, several die-casters never converted to SF_6, and their experience shows that the gas can be applied without environmental problems.

Wrought Products. Wrought products are obtained by working a metal into the desired shape. Although the cold-forming properties of magnesium are very limited because of its hexagonal structure, magnesium alloys can be hot-worked readily by most of the well-known methods, such as extrusion, rolling, and forging.

Extrusion [36]. Extrusion presses designed for aluminum alloys can, after minor modifications of tooling, extrusion speed, and billet temperature, be used to extrude magnesium alloys. Compared with the 6000 series aluminum alloys, most magnesium alloys require a higher extrusion pressure (850 – 900 MPa) and thus a container of slightly smaller diameter. Magnesium alloys respond differently to extrusion speed. Alloys containing relatively large amounts of aluminum, such as AZ61A and AZ80A, are limited to maximum speeds of 5 and 3 m/min, respectively. At higher speed the temperature of the extrusion increases and hot cracking may occur. The AZ31B alloy, however, is extruded at speeds up to 20 m/min. As a general rule, an increase in the total amount of alloying elements results in lower extrusion speed. For some alloys (e.g., ZM21) an increase in extrusion speed results in lower mechanical properties. Therefore, selection of extrusion parameters is frequently a compromise between properties and productivity. Currently, AZ31B is the most popular moderate-strength extrusion alloy; AZ61A and AZ80A have higher mechanical properties and are often artificially aged for additional strength. The zirconium-containing alloys ZK40A and ZK60A are used when the yield strength is of prime importance. A new Mg – Zn – Cu – Mn alloy, ZCM711, is heat treatable to tensile yield strength values as high as 350 MPa in the T6 temper [14].

Rolling. Magnesium alloys rolled on conventional equipment are available commercially as flat sheet and plate, tooling plate, and tread plate [15]. Specialty items such as photoengraving sheet and plate, mechanical engraving plate, and electrochemical sheet are also available. Fine grain size and a good dispersion of any second phase are necessary for good rollability. Therefore, zirconium-containing alloys and the single-phase M1A alloy roll well.

Forging. In forging, the metal is worked with hammers and presses. Magnesium is one of the more forgeable metals. Of all magnesium product forms, forgings have the best combination of mechanical properties. They are also pressure-tight and have excellent machinability.

5. Manufacture of Articles from Magnesium Alloys

Magnesium products offer many advantages to the designer of light structures. In addition to the obvious weight-saving benefit, magnesium products provide manufacturing advantages such as excellent castability, good hot forming of wrought products, high weld efficiency, and unsurpassed machinability.

5.1. Shaping

Machining. Magnesium and magnesium alloys are the easiest of all metals to machine, permitting machining operations at extremely high speed. All standard machining operations such as turning, drilling, milling, tapping, threading, counterboring, reaming, sawing, and grinding

are commonly performed on magnesium parts. Deeper cuts can be made and higher feed rates used than with other metals. The life of high-speed steel cutting tools for magnesium equals that of carbide-tipped tools used for other metals. The excellent surface finish of machined magnesium is the result of its minimal tearing and dragging tendencies. The free cutting characteristic of magnesium produces well-broken chips that do not obstruct the cutting tool or machine. Standard machining operations produce extremely good tolerances. The power requirements to remove a given volume of metal are lower for magnesium than for any other metal; removable volumes are 0.024, 0.082, and $0.150\,cm^3\,W^{-1}\,min^{-1}$ for mild steel, aluminum, and magnesium, respectively.

A major difference with regard to other metals is that dry machining of magnesium is common practice. In especially difficult operations a coolant such as compressed air or mineral oil is sometimes used to assist in chip removal or to cool the workpiece. Some high-volume machining of magnesium automobile parts is performed with inhibited aqueous coolants, which are mandatory to retard the formation of hydrogen by reaction of magnesium with water.

When grinding or polishing magnesium, special care must be taken to avoid ignition of fine particles; fine dust should be collected in water-washed dust collectors.

Forming. Because of their hexagonal crystal structure, the cold forming of magnesium alloys is restricted to mild deformation and generous bend radii (bend radius : material thickness > 2). However, above 200 °C magnesium becomes very workable; formability at 200 – 300 °C improves to such an extent that more severe working is possible than with other metals at room temperature. (The workability of the cubic system metals is not greatly enhanced by increasing temperature.)

Working of metals at elevated temperature has several advantages over cold working. In some configurations, magnesium can be formed in one operation, thus avoiding repeated annealing and reforming, and reducing production time. Hot-formed parts are made to closer dimensional tolerances because of reduced springback.

5.2. Joining

Magnesium alloys are joined by all conventional methods including welding, brazing, soldering, adhesive bonding, riveting, and bolting.

Welding is carried out almost exclusively by the tungsten inert gas and the metal inert gas methods. In general, weld efficiencies are high.

In magnesium alloys the success or reliability of *adhesive bonding* depends greatly on the environment to which the parts are to be exposed. A conversion coating is required before joining. When exposed to severe environments such as salt and moisture, joints must be sealed. A combination of adhesive bonding and riveting is sometimes used.

Riveting is widely used for making mechanical joints. Standard rivet shapes are employed, spaced so that the distance between them does not exceed three times the rivet diameter. Aluminum 5000 series alloy rivets are preferred. When bolts, screws, and similar standard fasteners are used to join magnesium to other metals and materials, particular attention is given to joint design and the avoidance of galvanic corrosion.

5.3. Finishing

As with other structural metals, magnesium alloys are given a variety of surface treatments for decorative, functional, or protective purposes. Processes are available to meet almost any practical requirement, including chemical and electrochemical conversion coatings, wet painting, resin powder coating, and electroless nickel or electrolytic metal plating [5].

In some applications, relatively comprehensive surface treatments are specified. Choice of treatment depends upon the ultimate use of the product with regard to corrosion, wear, durability, and appearance.

Mechanical Preparation. The usual methods such as belt sanding, wheel grinding, polishing, brushing, buffing, blasting, and barrel or vibratory finishing are applied to magnesium products. Vibratory finishing with ceramic or resin-bonded chips is widely used in mass production for both deburring and smoothing purposes.

Grinding, polishing, and buffing methods used for aluminum and zinc are also used with magnesium. Because of its natural tendency to tarnish, polishing and buffing are used only to prepare magnesium alloy surfaces for plating or for clear lacquering.

Dry blasting of magnesium is usually avoided because most of the commonly used blasting media contaminate the surface with cathodic particles, resulting in deterioration of corrosion resistance. The least adverse effects are experienced with cut 5000 series aluminum alloy wire, which has a low iron and copper content. To remove surface contamination, blasting is followed by acid pickling which removes at least 0.05 mm of the prepared surface.

To minimize fire hazards, magnesium dust must not be allowed to accumulate in the working area, in suction ducts or pipes, or on operators' clothing. Well-grounded, explosion-proof equipment is used in conjunction with approved wet-type dust collectors.

Cleaning. The most common methods used for cleaning magnesium are alkaline cleaning and acid pickling (→ Metals, Surface Treatment). Because of the alkali resistance of most magnesium alloys, proprietary steel cleaners based on alkali metal hydroxides, carbonates, silicates, and pyrophosphates are normally suitable for magnesium. Acid pickling is used to remove surface contamination by sand particles, corrosion products, residues from blasting, chromate coatings, and burned-on lubricants.

Conversion Coatings. Conversion coatings react with the alloy surface to convert it into a component of the coating. Their primary function is to improve the adhesion of organic coatings and to prevent undercutting in corrosive environments at sites where the coating has become damaged. Chromate conversion coatings are most commonly used (→ Electrochemical and Chemical Deposition, Chap. 11.). Certain phosphate conversion coatings provide a satisfactory paint base for many corrosive environments [16] (→ Metals, Surface Treatment). Phosphate treatment has been used for many years as a base for organic coating of extruded and die-cast magnesium luggage frames [37]. Anodic coatings are used when a heavy-duty paint base or added protection against wear is required [17] (→ Electrochemical and Chemical Deposition, Chap. 12.2.2.).

Organic Coatings. Various types of organic coatings can be applied to magnesium alloys by conventional methods. However, consideration must be given to the alkaline nature and electrochemical properties of the metal in selecting primer vehicles and pigments; an alkali-resistant binder and suitable pigmentation must be used. To achieve optimum protection against corrosion, inclusions from blasting processes should be removed by acid pickling before further chromate and finishing steps are taken.

Use of a high-purity alloy is necessary to obtain maximum corrosion protection, especially where damage from stone chipping and scratches is likely to occur. The corrosion properties of painted high-purity alloy AZ91D and ordinary AZ91B are compared in Table 4.

Primers used on magnesium alloys should be based on alkali-resistant vehicles (e.g., vinyl, epoxy, polyvinylbutyral, acrylic, polyurethane, and vinyl epoxy). Zinc chromate and strontium chromate are commonly used pigments, whereas aluminum, zinc, lead, or iron pigments are avoided. For application above 200 °C, primer and paint vehicles based on silicone, epoxy–silicone, or polyimide are used. Cathodic (cataphoretic) electropainting is used on magnesium both as a primer and as a final finish (e.g., for automotive grills and small computer parts). For a detailed description of paints, see → Paints and Coatings.

Plating [5], [18]. Most cast or wrought magnesium alloys can be electroplated. The basic process is similar to the plating of aluminum in that both alloys are given a zinc immersion coating prior to plating (→ Electrochemical and Chemical Deposition, Chap. 5.3.6.).

6. Corrosion and Corrosion Control

(→ Corrosion)

Factors that affect the corrosion properties of magnesium are alloy composition, heavy-metal impurities, casting variables, metallographic structure, environment, surface condition, and contact with other materials. Thermodynamically, magnesium should react completely with

Table 4. Salt spray performance of painted die-cast AZ91B (standard) and AZ91D (high-purity) test panels (DIN 53 167)

Alloy	Paint system ∗	Exposure time, h	Scribe corrosion creepage, mm	Stone chip resistance rating no.∗∗

oxygen and with water. The fact that it does neither is caused by passive behavior in many environments. In a corrosive environment, pitting or other forms of local corrosion occur as a result of film breakdown.

Magnesium alloys of suitable composition (see Section 6.1) and purity are corrosion resistant and are used successfully in a variety of applications. Automotive parts made of commercial high-purity die-cast AZ91D alloy located in the worst splash zone under a car illustrate the excellent corrosion resistance of magnesium [19].

6.1. Effect of Composition and Structure

Composition. The corrosion of magnesium alloys is commonly measured in salt solution either as continuous salt spray or in cyclic corrosion tests. For the latter, the samples are exposed to combinations of salt spray, high humidity, and drying conditions. These tests are designed to simulate real-life exposure.

Most of the elements present in, or added to, magnesium alloys have limited solid solubility in the alloy and therefore occur as precipitated phases. In virtually all cases, these phases are more noble (i.e., have a higher redox potential) than the matrix. Their influence on saltwater corrosion depends heavily on their potential relative to the matrix and their efficiency as cathodic sites, i.e., the ease with which they liberate hydrogen gas (overvoltage) [20].

The elements generally present in commercial magnesium alloys that influence saltwater corrosion can be classified as follows:

1) Generally benign or beneficial: aluminum, beryllium, manganese, rare earth metals, silicon, zinc, and zirconium
2) Moderately deleterious: silver
3) Severely deleterious: nickel (and cobalt), iron, and copper

The commercially important Mg – Al – Zn alloys used for die casting and sand casting have received intensive study [21], [22], resulting in the development of alloys with outstanding saltwater corrosion resistance. These alloys have a very low critical impurity content (Ni, Fe, Cu) and a controlled manganese content.

Structure. The size and distribution of the cathodic phases play an important role in corrosion and are influenced by process parameters and heat treatment. The influence of microstructure on the corrosion of die-cast AZ91D is described in [48]. Homogenized and artificially aged specimens of AZ91E (T6) show considerably lower corrosion than cast (F) and homogenized (T4) specimens [23]. Heat treatment influences mainly the distribution of the intermetallic β-phase ($Mg_{17}Al_{12}$) in the alloy. Aging to T6 temper causes precipitation of this phase as an almost continuous network of secondary particles along the grain boundaries. In the T4 condition the β-phase is fully dissolved. By air cooling from T4, only traces of β-phases can have the same effect as a full T6 treatment. Tolerance limits in cast magnesium alloys for the most important impurity elements (iron, copper, and nickel) are influenced by the cooling rate and the amount of manganese present [21], [22], [24], [38]. In the early stages of corrosion, filiform attack develops from an initiating pit adjacent to intermetallic particles [25], [26], and the

role of $Mg_{17}Al_{12}$ concentrated in grain boundaries can be clearly illustrated. Cold working of magnesium alloys (e.g., by stretching or bending) has no appreciable effect on corrosion rate [4].

Surface Contamination. Producers of magnesium have demonstrated the importance of high-purity alloys for structural applications. However, surface contamination from handling and mechanical treatment can destroy the corrosion resistance of high-purity alloys. This helps explain why ceramic blasting media containing iron oxide can be just as harmful to the corrosion properties of magnesium as steel grit.

6.2. Effect of the Environment

Atmosphere. A magnesium alloy surface exposed to a salt-free atmosphere develops a gray film consisting mainly of magnesium hydroxide that protects the metal from corrosion. Chlorides, sulfates, or other hydrophilic substances promote corrosion by destroying this film. Structural magnesium alloys are resistant to rural atmospheres and moderately resistant to industrial or mild marine atmospheres. The corrosion rate in marine atmospheres is significantly lower for the high-purity Mg – Al – Zn alloys.

Water. When magnesium is immersed in distilled water without the possibility of carbon dioxide absorption, the initial corrosion rate decreases rapidly to a very low value. A protective film of magnesium hydroxide forms on the surface. The solubility product of magnesium hydroxide in the solution is quickly reached, dissolution of the hydroxide is inhibited, and corrosion essentially stops. If the water is replenished, corrosion continues and increases on absorption of carbon dioxide due to dissolution of the protective film. Raising the temperature of distilled or natural water also increases the corrosion rate of magnesium alloys. Aluminum is beneficial as an alloying ingredient because it promotes the formation of protective hydrotalcite $[Mg_6Al_2(OH)_{16}CO_3 \cdot 4\,H_2O]$ films.

Acids. Magnesium is attacked by all acids except hydrofluoric or chromic acid. Passive films are formed in most concentrations of these acids, accounting for their use in many conversion coating processes.

Salt Solutions. Neutral solutions of salts of heavy metals such as nickel, iron, and copper are corrosive to magnesium alloys.

Other Media. The behavior of magnesium in contact with a large number of substances at room temperature is described in [2]. Being an alkaline-earth metal, magnesium is stable in most basic and neutral solutions. Its strong affinity for fluorine and the nature of the resulting passive film (mainly magnesium hydroxide with some magnesium fluoride) account for the extremely low corrosion of magnesium alloys in most fluoride-containing electrolytes. Magnesium is stable in the presence of most organic compounds. However, methanol, being slightly acidic, attacks magnesium rapidly unless enough water is present ($> 0.5\,\%$) to passivate the surface. Magnesium can be safely and effectively cleaned with chlorinated organic solvents.

6.3. Galvanic Corrosion [27], [49]

Two conditions must be satisfied for galvanic corrosion to occur: (1) dissimilar metal-to-metal contact and (2) bridging of the bimetal junction by a conductive solution (electrolyte). The electrochemical process that normally occurs at the galvanic couple containing magnesium is:

$$\text{Anode: Mg (metal)} \rightarrow Mg^{2+} + 2\,e^-$$
$$\text{Cathode: } 2\,H_2O + 2\,e^- \rightarrow H_2 + 2\,(OH)^-$$

In salt environments, the high solubility and acidic nature of the magnesium chloride formed at the anode can result in rapid penetration of magnesium alloys.

Proper protection against galvanic corrosion begins with good design [2], [4]. This includes good drainage to prevent entrapment of electrolyte. Furthermore selection of the most compatible metals, sealing of faying surfaces, small ratios of cathode to anode area, and use of alkali-resistant barrier coatings are important.

The closest approach to compatibility with magnesium is provided by aluminum alloys of

Table 5. Average annual shipments of primary magnesium according to major end use in free market countries ∗

End use	Average annual shipments, 10^3 t		Market distribution, %	
	1995	1999	1995	1999

∗ As reported by the International Magnesium Association, McLean, Virginia.

the 5000 – 6000 series, and nowadays fasteners made of AA6013 are available [39]. Tin, cadmium, and zinc platings on steel fasteners reduce galvanic action on magnesium in salt spray by 60 – 70 %, which is sufficient for many practical applications. Supplementary polymer coatings and inorganic sealers can reduce galvanic corrosion further [40], [41]. A combination of properly plated steel fasteners and aluminum washers has proven to be very efficient in preventing galvanic corrosion.

Additional resistance in the metallic or electrolytic portions of the galvanic cell circuit can reduce or eliminate galvanic current flow. Such resistance can be supplied by insulating materials such as nonmetallic bolts, insulating washers or tapes, or organic coatings.

The combination of a small magnesium anode and a large cathode area can lead to intense corrosion penetration of the magnesium. In painting a galvanic couple, the cathode or the entire couple must be coated. In no case should the magnesium alone be coated. Small areas of magnesium exposed by paint defects or scratches could be subjected to intense corrosion penetration.

7. Environmental Aspects

The Swedish Ecocycle Commission of 1997 [42] gave magnesium, together with three other metals, a positive evaluation with respect to sustainability criteria such as resource friendliness, recyclability, and toxicity.

Mining of magnesium-containing raw materials such as dolomite and magnesite affects limited areas, and there are no significant disposal or effluent problems. The minerals are transported to the plants by sea. Electrical energy is used in electrolysis. In addition some steam and fossil fuels are used in the process.

The main contribution to the equivalent total CO_2 emission from magnesium production is the use of SF_6 as a cover gas to protect liquid metal surfaces from oxidation in casting operation. SF_6 is nontoxic and odorless but has a strong Global Warming Potential (GWP = 23 900). There is a significant focus on reducing the use of SF_6 in the magnesium industry.

Solid waste consists mostly of inorganic salts and minerals from raw materials. Magnesium process scrap (class 1) is recycled. Typically 30 – 50 % of the shot weight from die casting of magnesium alloys is sorted into various scrap classes and recycled.

In spite of the relatively high demands for energy and natural resources in the production of light metals, the use of these materials in components for light vehicles has a net positive environmental effect compared with the materials and parts which they displace. A comparison of the environmental impact of magnesium and

competing automotive materials is described in terms of relative energy consumption throughout the lifetime of a passenger car [43].

8. Economic Aspects [1–3], [45]

About 40 % of the primary magnesium produced in the free-market countries is consumed in the form of magnesium alloys used in structural and electrochemical applications. For statistics covering world production and consumption of primary magnesium, see → Magnesium, Chap. 8.

The major end uses for magnesium and magnesium alloys are listed in Table 5. The use of magnesium alloys in aerospace and military applications has declined, but has been compensated by growth in commercial applications such as pressure die castings used in automobiles and computers. Electrochemical applications of magnesium alloys include anodes for cathodic protection, photoengraving plates, and seawater batteries (primary batteries in which seawater is the primary electrolyte, used in sonobuoys and torpedoes).

1. Introduction

Magnesium occurs in divalent form in all of its compounds. The bromide, iodide, sulfate, and nitrate salts are water soluble. Some of the water-soluble salts are highly hygroscopic and form crystals with a high water content. Magnesium fluoride, oxide, hydroxide, phosphate, and carbonate are sparingly soluble or insoluble in water.

The water-soluble magnesium salts tend to undergo hydrolysis and form basic salts due to the weakly basic character of magnesium hydroxide. This is responsible for the highly corrosive action of magnesium salt solutions; dehydration of magnesium salts containing water of crystallization without hydrolytic decomposition is also difficult to achieve.

The most important magnesium compounds are magnesium oxide, which is used for refractory magnesia bricks and as a heat-storage medium, and magnesium chloride which is electrolyzed to produce magnesium metal. Naturally occurring magnesium carbonate (magnesite) is mainly burned to give sintered magnesia for the production of magnesia bricks. Seawater is an important source of magnesium oxide and magnesium chloride. Calcined dolomite ($CaCO_3 \cdot MgCO_3$) is used as a raw material for the silicothermic production of magnesium metal (→ Magnesium). Basic magnesium carbonate is used for thermal insulation.

Anhydrous magnesium nitrate [*10377-60-3*] is difficult to produce (*mp* of the hexahydrate [*13446-18-9*] 89 °C). Concentrated magnesium nitrate solutions (e.g., from $MgCO_3$ and 60 % nitric acid) are used for the production of highly concentrated nitric acid (→ Nitric Acid, Nitrous Acid, and Nitrogen Oxides).

Naturally occurring magnesium silicates include asbestos (→ Asbestos) and talc (→ Talc). Materials for electrical insulation are also based on magnesium silicates (→ Insulation, Electric, Chap. 3.1.2.2., → Insulation, Electric, Chap. 3.1.2.3.). A series of refractory ceramics are based on magnesium (→ Refractory Ceramics).

Organomagnesium compounds are also known, the most important of these being the Grignard reagents which play an important role in synthetic organic chemistry.

Other magnesium compounds are dealt with elsewhere in the Encyclopedia: magnesium cyanide, → Cyanide Compounds, Inorganic, Chap. 2.2.; magnesium fluoride, → Fluorine Compounds, Inorganic, Chap. 4.4.; magnesium hydride, → Hydrides, Chap. 2.6.; magnesium ammonium phosphate, → Fertilizers, Chap. 4.4.4.

2. Magnesium Carbonate

Properties.

Anhydrous magnesium carbonate [*13717-00-5*], $MgCO_3$, M_r 84.33, occurs naturally as *magnesite* which is the starting material for the production of magnesia, MgO (see Section 4.2). Magnesium carbonate is also synthesized by reacting $Mg(OH)_2$ with carbon dioxide at high pressure [1]. Magnesium carbonate begins to decompose at ca. 400 °C, the reaction proceeds rapidly above 550 °C. The compound forms colorless or white to gray, trigonal crystals: lattice constant $a = 0.585$ nm, $\alpha = 103°20'$, $Z = 4$, cleavage parallel to $(10\bar{1}1)$.

Density	2.96 g/cm^3
Mohs hardness	4 – 4.5
Refractive index	n_0 1.700, n_ε 1.509
Enthalpy of formation (298 K)	− 1096 kJ/mol
Dissociation energy (298 K)	+ 1190 kJ/kg
Solubility in cold water	0.0106 wt %

Barringtonite [*5145-48-2*], $MgCO_3 \cdot 2\,H_2O$, M_r 120.35, forms colorless triclinic crystals, lattice constants $a = 0.9115$ nm, $b = 0.6202$ nm, $c = 0.6092$ nm; $\alpha = 94.00°$, $\beta = 95.53°$, $\gamma = 108.87°$; $Z = 4$; refractive index 1.458, 1.473, 1.501; density 2.83 g/cm^3.

The mineral *nesquehonite* [*14457-83-1*], $MgCO_3 \cdot 3\,H_2O$, M_r 138.37, occurs as colorless to white crystals. This carbonate can also be synthesized by carbonation of $Mg(OH)_2$ at atmospheric pressure. Density 1.84 g/cm^3, *mp* 165 °C (decomp.), solubility in cold water 0.129 wt %.

Lansfordite [*61042-72-6*], $MgCO_3 \cdot 5\,H_2O$, M_r 174.40, forms white monoclinic crystals, density 1.73 g/cm^3.

The natural mineral *hydromagnesite* [*12072-90-1*], $4\,MgCO_3 \cdot Mg(OH)_2 \cdot 4\,H_2O$, M_r 467.67, forms white monoclinic crystals,

density 2.25 g/cm^3 [2]. The synthetic product is known as magnesia alba.

Other $MgCO_3$-containing minerals include *huntite* [*19569-21-2*], $CaCO_3 \cdot 3\ MgCO_3$, M_r 353.05 [2], and *dolomite* [*16389-88-1*] $CaCO_3 \cdot MgCO_3$, M_r 184.41. Dolomite is a rock-forming mineral and is much more common than magnesite. It is burned to form sintered dolomite (for refractory bricks) and light-burned dolomite (used as a fluxing agent).

Uses. The main use of magnesite is the production of magnesia (Section 4.2). Small quantities are used as a filler. Plans have been proposed for producing magnesium metal from naturally occurring (cheap) magnesite [3]. The synthetic carbonates are used as fillers for paper, plastics, and rubber and as thickening agents for printing inks. Pharmaceutical-grade magnesium carbonate (magnesia alba) is also used in toothpaste and as an antacid. High-purity magnesium carbonate is employed in cosmetics.

3. Magnesium Chloride

Magnesium chloride [*7786-30-3*], $MgCl_2$, is the most common naturally occurring, water-soluble magnesium compound. It is a constituent of many salt lakes and natural brines [4], [5]; sea salt contains 17 wt % $MgCl_2$. Mineral salt deposits contain the important minerals carnallite [*1318-27-0*] $KCl \cdot MgCl_2 \cdot 6\,H_2O$, bischofite [*7791-18-6*] $MgCl_2 \cdot 6\,H_2O$, and occasionally the double salt tachhydrite in which the magnesium chloride is combined with calcium chloride ($CaCl_2 \cdot 2\,MgCl_2 \cdot 12\,H_2O$). Tachhydrite is found in salt deposits in Brazil and the Congo region.

Magnesium chloride is obtained from mineral salt deposits by processing the spent liquors remaining after extraction of potassium chloride and also by direct solution mining; it is also recovered from salt lakes and seawater.

3.1. Properties

Anhydrous Magnesium Chloride. Anhydrous magnesium chloride forms hexagonal crystals, its physical properties are as follows:

M_r	95.23	
mp	713 °C	
Refractive index (*n*)	1.675, 1.59	
d_4^{20}	2.41 g/cm^3	
Specific heat (c_p) between 0 and 713 °C (*mp*):		
$c_p = 0.78011 + 0.20607 \times 10^{-3} \times (t-20) - 0.10853 \times 10^{-6} \times (t-20)^2$ kJ kg^{-1} K^{-1} (t in °C)		
Specific electrical conductivity at		
700 °C	1.00 Ω^{-1} cm^{-1}	
750 °C	1.09 Ω^{-1} cm^{-1}	
800 °C	1.17 Ω^{-1} cm^{-1}	
Solubility in water at		
20 °C	35.3 wt %	54.6 g/100 g
40 °C	36.5 wt %	57.5 g/100 g
60 °C	37.9 wt %	61.0 g/100 g
80 °C	39.8 wt %	66.1 g/100 g
100 °C	42.2 wt %	73.0 g/100 g
Solubility in methanol at		
0 °C	15.5 g/100 g	
60 °C	20.4 g/100 g	
Solubility in ethanol at		
0 °C	3.61 g/100 g	
60 °C	15.89 g/100 g	

Properties of the Hydrates. Magnesium chloride forms five hydrates whose transformation temperatures and solubilities are given in Table 1 (see also Fig. 1). The most important is the hexahydrate, $MgCl_2 \cdot 6\,H_2O$, which forms monoclinic crystals and is present in mineral salt deposits:

M_r	203.31
mp	117 °C
Heat of fusion	34.3 kJ/mol
Density	1.57 g/cm^3
Refractive index (*n*)	1.495, 1.507, 1.528
Specific heat (c_p) at 48.6 °C	1.415 kJ kg^{-1} K^{-1},
100 °C	1.537 kJ kg^{-1} K^{-1}

Table 1. Transformation temperatures and corresponding solubilities of magnesium chloride hydrates

Hydrate transformation	Temperature, °C	Solubility, g $MgCl_2$/100 g H_2O
$MgCl_2$ solution→$MgCl_2 \cdot 12\,H_2O$	− 33.6	27.2
$MgCl_2 \cdot 12\,H_2O$→$MgCl_2 \cdot 8\,H_2O$	− 17.4	47.6
$MgCl_2 \cdot 8\,H_2O$→$MgCl_2 \cdot 6\,H_2O$	− 3.4	52.3
$MgCl_2 \cdot 6\,H_2O$→$MgCl_2 \cdot 4\,H_2O$	116.8	85.6
$MgCl_2 \cdot 4\,H_2O$→$MgCl_2 \cdot 2\,H_2O$	181.5	125.7

The penta- and hexahydrates can be dehydrated to the tetrahydrate stage almost without decomposition. On dehydration to the dihydrate,

however, hydrolytic decomposition starts. Dehydration of the dihydrate at 240 °C leads to extensive decomposition forming magnesium oxychlorides or oxide. To obtain anhydrous $MgCl_2$, the dihydrate must be dehydrated in an atmosphere of hydrogen chloride.

Figure 1. State diagram of the system $MgCl_2 \cdot n\,H_2O$

Chemical Properties. Magnesium chloride can be decomposed by oxygen to form magnesium oxide and chlorine [6] – the converse of the reaction between magnesium oxide and chlorine to form $MgCl_2$. With ammonia, $MgCl_2$ forms ammines that are analogous to the hydrates: $MgCl_2 \cdot NH_3$, $MgCl_2 \cdot 2\,NH_3$, and $MgCl_2 \cdot 6\,NH_3$. Corresponding addition compounds are formed with alcohols and with other organic compounds such as ethers, acetic acid, amines, ethyl acetate, pyridine, hexamethylenetetramine, and dioxane (e.g., $MgCl_2 \cdot 6\,CH_3COOH$).

A series of basic chlorides (magnesium oxychlorides) are formed with magnesium oxide and are of commercial importance as Sorel cement (see 3.8). The following oxychlorides are known: $MgCl_2 \cdot MgO$, $MgCl_2 \cdot MgO \cdot H_2O$, $2\,MgCl_2 \cdot MgO \cdot H_2O$, $MgCl_2 \cdot 3\,MgO \cdot 11\,H_2O$, and $MgCl_2 \cdot 3\,MgO \cdot 7\,H_2O$. The compounds $MgCl_2 \cdot MgO$ and $2\,MgCl_2 \cdot MgO \cdot H_2O$ are formed on dehydration of $MgCl_2 \cdot H_2O$ at 280–495 °C. Aqueous $MgCl_2$ solutions are weakly acidic due to hydrolysis. The electrolysis of aqueous $MgCl_2$ solutions produces magnesium hydroxide and chlorine, whereas electrolysis of anhydrous $MgCl_2$ yields magnesium metal and chlorine.

3.2. Raw Materials

Of the three main sources of raw materials for magnesium chloride production, the most important is *seawater*. Magnesium can be directly precipitated from seawater as magnesium hydroxide and converted to magnesium chloride by treatment with chlorine. The residues (bitterns) obtained after production of drinking water or sea salt from seawater can also be used. A second large source is the *spent liquor from the potash industry* arising from the processing of hard salts and carnallite-bearing raw materials. A third source is provided by the *salt lakes* in many parts of the world, the Dead Sea and the Great Salt Lake being particularly important.

3.3. Production

3.3.1. Precipitation of Magnesium Hydroxide from Seawater

If seawater cannot be preconcentrated by solar energy, magnesium chloride salts or solutions can only be produced on a large scale by precipitation as the hydroxide, followed by conversion to the chloride with hydrogen chloride.

The Dow Chemical process is described elsewhere (→ Magnesium). This process has been used to manufacture magnesium chloride from seawater in large quantities since 1941 in Freeport (Texas). It is an intermediate step in the production of magnesium metal.

3.3.2. Recovery from Spent Liquors from the Potash Industry

The spent liquors obtained after recovery of potassium chloride from carnallite-containing raw salts (→ Potassium Compounds) typically contain (in grams per liter): $MgCl_2$ 293, $MgSO_4$ 48, KCl 39, NaCl 26, and H_2O 890. They are used as a raw material for the recovery of magnesium chloride. For the Norsk Hydro process, see → Magnesium.

Production of Concentrated $MgCl_2$ Solutions by Kali und Salz AG (Germany). The spent liquor contains ca. 280 – 300 g/L $MgCl_2$ and is concentrated in a two-stage vacuum evaporator to ca. 460 g/L $MgCl_2$. (Vapor pressures of $MgCl_2$ solutions as a function of concentration and temperature are shown in Fig. 2).

Figure 2. Vapor pressure of $MgCl_2$ solutions as a function of temperature

The solution in the first evaporator stage is heated by the vapor from the second stage to a steady temperature of ca. 55 °C. The second-stage liquor is maintained at 95 °C by heating with steam at 0.1 MPa and the hot, cloudy solution is clarified by removing the salts [carnallite, NaCl, $MgSO_4 \cdot 5/4\ H_2O$, and impurities such as $Fe(OH)_3$ and clay] by means of a rotary filter and centrifuge. On cooling carnallite crystallizes from the solution. The crystallized salts and sludge are sent to the potassium chloride plant where carnallite is decomposed together with carnallite containing crude potash salt. The carnallite is mixed with water or a low-$MgCl_2$ brine to produce a spent liquor containing 280 – 300 g/L of $MgCl_2$ and solid potassium chloride contaminated with sodium chloride and $MgSO_4 \cdot 5/4\ H_2O$ (→ Potassium Compounds). The cooled $MgCl_2$ solution can be purified by reheating and removing bromine with chlorine. In this case the debrominated solution is neutralized with lime, partly precipitating the sulfate ions in the form of gypsum. The precipitated sediment is removed. The highly concentrated 32 – 33 % $MgCl_2$ solution is sold as such (see Section 3.5) or can be processed further to obtain magnesium chloride hydrates (see Section 3.3.6).

Production of Concentrated $MgCl_2$ Solution by the VEB Kombinat Kali (former German Democratic Republic). The spent liquor from the manufacture of potassium salts had a $MgCl_2$ content of ca. 260 g/L. The solution was first mixed with synthetic carnallite from the vacuum cooling stage; the $MgCl_2$ from the carnallite dissolves leaving the undissolved potassium chloride behind. The increased $MgCl_2$ content (ca. 320 g/L) of the solution lowers the solubility of the alkali-metal salts causing the precipitation of potassium and sodium chlorides. After removal of these salts, the solution was pumped to the second of the two evaporation stages. The preconcentrated solution from the second evaporation stage was pumped to the first evaporation stage where $MgSO_4 \cdot 5/4\ H_2O$ precipitates together with some langbeinite, carnallite, and sodium chloride. On cooling this solution, (after removal of the salts) in multistage vacuum coolers, synthetic carnallite precipitates. The carnallite was filtered off and recycled to the first step of the process. All the evaporators were of the forced circulation type [7]. The first evaporator stage was operated at 120 °C and heated with steam. The second stage was heated to 80 °C by the vapor from the first stage. The vapors from the second stage were cooled with water.

In a variation of the process, the solution containing 320 g/L $MgCl_2$ was mixed with part of the product solution (containing 460 g/L $MgCl_2$). The increase in the $MgCl_2$ content causes more sodium chloride and carnallite to precipitate. Evaporation of the solution from the first stages then does not precipitate carnallite or langbeinite ($K_2SO_4 \cdot 2\ MgSO_4$). Only synthetic kieserite ($MgSO_4 \cdot 5/4\ H_2O$) and sodium chloride are precipitated and these are removed. The solution produced had a density of 1.340 g/cm^3 and contained 460 g/L $MgCl_2$, 25 g/L $MgSO_4$, 2 g/L KCl, 6 g/L NaCl, 2 g/L $CaSO_4$, and 4 g/L Br^-. If these solutions are used for the production of magnesium metal, they must be debrominated with chlorine (→ Bromine, Chap. 4.). If they are used for production of high-quality sintered magnesia, boron is also removed by boron-selective resins. The boron content decreases from 30 to 5 –10 mg/L [8].

Recovery from Raw Salts Containing Carnallite. Patents have been applied for in which pure carnallite or raw salts containing carnallite are decomposed with C_1–C_4 alcohols, causing the $MgCl_2$ to pass into the alcohol phase [9]. The alcoholic solution is concentrated by evaporation to an alcohol content of 10 %, and the hexahydrate is precipitated by addition of water. Alternatively, evaporation is continued until the solution contains 1 – 2 mol of alcohol per mole of $MgCl_2$; the alcoholate is then thermally decomposed in a hydrogen chloride atmosphere at 400 – 500 °C.

3.3.3. Evaporation of Seawater and Natural Brines

The direct production of $MgCl_2$ from seawater or brines by evaporation is only economical where the dilute solutions can be preconcentrated by solar evaporation (→ Sodium Chloride).

Recovery from the Dead Sea. Magnesium chloride-containing solutions are produced in large quantities by solar evaporation of brine from the Dead Sea. At the Dead Sea Works, carnallite precipitates in the final stage, and solutions containing 360 g/L $MgCl_2$, 110 g/L $CaCl_2$, 7 g/L NaCl, and 5 g/L KCl are obtained. Owing to the low vapor pressure of water, solar evaporation only occurs at very low atmospheric humidity levels. After two or three months of evaporation, a density of 1365 g/L is achieved and bischofite crystallizes [10]. Large quantities of $MgCl_2$-containing liquors of this type are now used by Dead Sea Periclase solely for the production of magnesium oxide by thermal decomposition.

In a process patented by the Dead Sea Works for the manufacture of magnesium chloride hexahydrate (bischofite), carnallite or a natural mixture of carnallite and sodium chloride is decomposed in its own water of crystallization in closed vessels under pressure at 167.5 °C. The potassium chloride remains together with the sodium chloride as a sediment and is removed. The residual solution contains up to 8.2 % potassium chloride and 42.3 % magnesium chloride. On cooling to 115 °C by flash evaporation, carnallite is precipitated and is fed back into the circulating system. The residual solution contains 1 % potassium chloride and consists essentially of bischofite [11].

Recovery from the Kara–Bogaz Gulf (Turkmenia). Following the isolation of the Kara-Bogaz Gulf from the rest of the Caspian Sea by a dam in 1979, the $MgCl_2$ content increased to 250 g/L. Research was carried out to find a new method of processing this brine [12]. The brines evaporated in summer contain 25 – 30 wt % $MgCl_2$. When they are cooled in winter, epsomite ($MgSO_4 \cdot 7\,H_2O$) precipitates and is used for producing schönite ($K_2SO_4 \cdot MgSO_4 \cdot 6\,H_2O$). The liquid phase is used for $MgCl_2$ production.

Recovery from Spent Liquors after Extraction of NaCl from Seawater. The spent liquors (sea bitterns) obtained after extraction of salt from seawater are evaporated in crystallizing pans by solar energy to a density of 1290 g/L. After removing the sodium chloride, the solution is cooled to 5 °C, which can be achieved in winter without energy consumption. Magnesium sulfate (epsomite) crystallizes with a few impurities and is removed. The bitterns are cooled to 0 °C; sodium sulfate (Glauber's salt) crystallizes and is removed. The solution is then debrominated with chlorine (→ Bromine, Chap. 4.) to exclude crystallization of magnesium bromide in subsequent processing. After neutralizing with potassium hydroxide, the liquor is heated to 125 °C. On cooling to 100 °C, a crude potassium-containing salt mixture separates that consists of langbeinite ($K_2SO_4 \cdot 2\,MgSO_4$) and kainite ($KCl \cdot MgSO_4 \cdot 3\,H_2O$), with some kieserite ($MgSO_4 \cdot H_2O$) and sodium chloride. On further cooling to 20 °C, carnallite crystallizes and can be treated with water to form a $MgCl_2$-containing solution and solid potassium chloride [13].

Recovery from the Great Salt Lake. For the National Lead Industries process, see → Magnesium. In the process operated by the Great Salt Lake Minerals Chemical Corporation, a 35-wt % $MgCl_2$ solution is first produced by solar evaporation, and this is then subjected to vacuum evaporation until bischofite ($MgCl_2 \cdot 6\,H_2O$) and hydrated $MgSO_4$ are

precipitated. Proposed further treatment consists of heating the crystals to 120 – 150 °C to redissolve the bischofite and allow removal of magnesium sulfate. The bischofite can then be crystallized [14]. Alternatively, the solution can be maintained at 120 °C until the magnesium sulfate content decreases to < 20 g/L as a result of crystallization of $MgSO_4 \cdot 5/4\,H_2O$. The bischofite is then crystallized by vacuum evaporation at 90 °C [15].

Recovery from Naturally Occurring Brines with High $CaCl_2$ Contents. Up to the end of World War II, the Dow Chemical Company used underground brines from Midland (Michigan) and Marysville for bromine production and also for the production of $MgCl_2$. The latter was electrolyzed to obtain magnesium. The alkali metal salts were removed by evaporation and crystallization. In an older process the calcium was then separated together with the magnesium as tachhydrite ($2\,MgCl_2 \cdot CaCl_2 \cdot 12\,H_2O$) which was converted into $MgCl_2 \cdot 6\,H_2O$. In a later process, the solution was reacted with an amount of magnesium hydroxide (produced from magnesite) equivalent to the calcium chloride content. The calcium was then removed as calcium carbonate by treating the solution with the carbon dioxide from the magnesite calcination, and the $MgCl_2$ was obtained from the solution.

Today, Dow obtains magnesium chloride for magnesium production only from seawater (→ Magnesium). The production of bischofite from Michigan brines has been discontinued.

3.3.4. Solution Mining

A 20-wt % $MgCl_2$ solution is produced in large quantities in the Netherlands from a carnallite salt deposit. It is used to produce concentrated $MgCl_2$ solutions and is converted to magnesium hydroxide (see Section 4.2.3) [16].

Solution Mining of Carnallite. Carnallite ($KCl \cdot MgCl \cdot 6\,H_2O$) deposits contain large amounts of magnesium sulfate as well as $MgCl_2$. Evaporation of solutions with high magnesium sulfate contents leads to precipitation of double salts containing sodium chloride and magnesium sulfate. In the processing of these solutions, most of the magnesium sulfate is precipitated as langbeinite ($K_2SO_4 \cdot 2\,MgSO_4$) [17], or as schönite ($K_2SO_4 \cdot MgSO_4 \cdot 6\,H_2O$) by precipitation with methanol [18]. In a process developed by the Mines de Potasse d'Alsace, a solution containing 320 g/L $MgCl_2$ can be obtained together with solid potassium chloride by solution mining. The solution used to extract the carnallite from the deposit contains a flotation agent for potassium chloride ($C_{12} - C_{20}$ fatty amines or their salts) and a gas-producing agent such as hydrogen peroxide. The potassium chloride floats and can be pumped out along with the $MgCl_2$ solution [19]. This production method appears promising, but it is not known whether large-scale development is planned.

3.3.5. Other Methods

Magnesium chloride can be produced from dolomite in combination with soda by the Solvay process. In the early part of World War II at a plant belonging to the Diamond Alkali Corporation in Painesville, Ohio, the dolomite was calcined in rotary furnaces, hydrated, and used to regenerate ammonia from the ammonium chloride solution produced in soda manufacture. Only the calcium hydroxide took part in the reaction. On treatment of the remaining solution with carbon dioxide, a magnesium chloride solution was obtained:

$$Mg(OH)_2 + CaCl_2 + CO_2 \rightarrow MgCl_2 + CaCO_3 + H_2O$$

This process is, however, no longer used.

In the Mathison Alkali Works, the calcium chloride solution from the soda process was treated with calcined dolomite while carbon dioxide was introduced. This process also produced a $MgCl_2$ solution but has been discontinued.

Calcined magnesite or magnesium hydroxide can also be used in the soda process to produce a $MgCl_2$ solution.

Processes are described in which magnesium chloride is produced from natural crude magnesite by leaching with hydrochloric acid, as well as the use of phosgene and crude hydrochloric acid with 27.5 % HCl and 1.2 % HF to treat magnesite and periclase [20–22].

3.3.6. Production of Magnesium Chloride Hydrates

Production of $MgCl_2 \cdot 6\,H_2O$ (Bischofite). In a process formerly used by Kali und Salz AG, end bittern from potash production was treated in a single-stage vacuum evaporator to produce a ca. 42-wt % $MgCl_2$ solution, and was further evaporated in pans with steam at 1.1 MPa. After neutralization with lime and removal of calcium sulfate, synthetic kieserite, and other impurities, the melt was fed onto rotating drum coolers or cooling bands to form a slab, which was broken up and marketed (see Section 3.5). Alternatively, after the initial single-stage evaporation, the solution can be prilled in a prilling tower or spray dried in a fluidized bed [23].

A very pure $MgCl_2$ hydrate with 4 – 6 molecules of water can be prepared in 99.9 % purity according to a patent of the VEB Kombinat Kali [24]. Carnallite is dehydrated at 180 – 200 °C and then cooled. The cooled salt is then treated with acetone, in which the $MgCl_2$ dissolves. After removal of the undissolved salt, the hydrate is precipitated from the acetone solution by adding the correct amount of water [24].

In a patent of the Mines de Potasse d'Alsace, $MgCl_2$ is precipitated from solution by addition of 10 – 25 % 1,4-dioxane at room temperature. At lower temperatures the yield of $MgCl_2$ is increased. The $MgCl_2$– dioxane complex separates as a voluminous precipitate that is easy to filter or centrifuge. It can be purified by washing with a little dioxane. The dioxane can be distilled off from the filtrate as an 80 % azeotrope and can be reused directly. The $MgCl_2$ hydrate can be obtained by washing with water. During drying the remaining dioxane (ca. 20 – 25 % of the total) is evaporated off and can also be reused [25].

Production of $MgCl_2 \cdot (2-3)H_2O$. In a process formerly used by Kali und Salz AG, a ca. 33-wt % $MgCl_2$ solution was heated to 110 – 130 °C and sprayed into a fluidized bed of magnesium chloride granules at 130 °C. The heating gas was at 400 – 600 °C. The average residence time of the granules is ca. 30 min. Fines and pulverized oversize granules were recirculated to the fluidized bed. The final product had a water content of ca. 30 % [23].

3.3.7. Production of Anhydrous Magnesium Chloride (See also → Magnesium, Chap. 4.1.1.)

The Nalco Chemical Company at its plant in Freeport, Texas, produces tetramethyl- and tetraethyllead. The Grignard reagents needed as intermediates for the process require a very pure source of magnesium. This is produced by the electrolysis of pure, anhydrous magnesium chloride, for which the following process has been developed.

Ethylene glycol is added with stirring to a 30 – 35-wt % $MgCl_2$ solution, the quantity added being sufficient to produce a 10 – 20-wt % $MgCl_2$ solution. All the water, including water of crystallization, is then removed by vacuum distillation. The distillate contains < 50 ppm ethylene glycol, and the residual solution contains < 25 ppm water together with all the other salts. Gaseous ammonia is then bubbled through the solution under slight pressure. The mixture is cooled to remove the evolved heat; in practice the temperature is allowed to rise to ca. 70 °C. When the glycol is saturated with ammonia, the hexaammine compound $MgCl_2 \cdot 6\,NH_3$ is formed. Towards the end of the reaction, the mixture is cooled to 15 – 30 °C, the $MgCl_2 \cdot 6\,NH_3$ precipitates and is filtered off. Any adhering solution is removed by washing with methanol. The ammonia and methanol are then removed in two stages: the methanol and some ammonia are first driven off at 74 °C. The rest of the ammonia is then removed in a calcination furnace at 400 °C [26].

As with the dehydration of carnallite, ammonium carnallite can be dehydrated almost without decomposition at 90 – 180 °C. It can then be decomposed at 180 – 400 °C to give ammonium chloride and anhydrous $MgCl_2$ [27], [28].

In the process developed by Esso Research, a 20 – 50-wt % solution of magnesium chloride reacts with ammonium chloride in a three-stage fluidized bed. Anhydrous magnesium chloride is produced at 350 – 550 °C [29].

In another process [30], ammonium carnallite containing $n\,NH_3$ or $n\,H_2O$ is decomposed at 800 °C. A product with a low magnesium oxide content is obtained. If the starting material contains water of crystallization, some is removed in a first stage, and further dehydration takes place

after adding ammonia. After the dehydration, the $MgCl_2 \cdot 6\,NH_3$ is thermally decomposed [31].

A process for the dehydration of magnesium chloride hydrates in a hydrogen chloride atmosphere is described in → Magnesium, Chap. 4.1.1.2..

3.3.8. Purification of Magnesium Chloride Solutions

Calcium ions can be removed from magnesium chloride solutions by adding the stoichiometric amount of sulfate ions [32]. Conversely, sulfate ions can be removed by adding calcium chloride solutions. Calcium and other metal ions can be extracted with dialkylphosphoric acid in a water-immiscible solvent. This process is used in the production of pure sintered magnesia from solutions of impure magnesites in hydrochloric acid [33]. These solutions can be treated with substances such as MgO, CaO, or $Mg(OH)_2$ to increase the pH, while simultaneously purging with air or oxygen at 80 – 90 °C. This removes impurities such as iron, aluminum, and manganese as hydrated oxides or hydroxides. This process is also used in the manufacture of pure sintered magnesia [34].

3.3.9. Materials of Construction for the Evaporation of Magnesium Chloride Solutions

At temperatures up to 110 °C, corrosion is usually prevented by the use of coatings, rubber linings, or plastic reinforced with glass fibers. Heater tubes and distillation trays are usually made of aluminum bronze ($AlBz_{5-7}$) as used in the potash industry, with a composition of 4 –8 % Al, 89 – 96 % Cu, and small amounts of Fe, Ni, Mn, As, Si, or Zn. Pumps are made of NiResist D 2.

Above 110 °C, and especially in the presence of chlorine and bromine (during debromination), glass and Teflon are suitable, with titanium being used for preheaters and pipework. According to [35] brick-lined steel vessels are used for evaporating $MgCl_2$ solutions and steam-heated tubes are made of Inconel alloy or stainless steel 347. Monel metal is also used for > 50 % $MgCl_2$ solutions.

3.4. Environmental and Legal Aspects

Magnesium chloride is a constituent of seawater. In the EEC Regulations (May 4th 1976) concerning disposal of hazardous substances in lakes and rivers, this substance is not mentioned. However, if large quantities are discharged into lakes or rivers, the concentration can be high enough to injure aquatic organisms and immediate dilution must be carried out. The WHO international standard for drinking water for magnesium is 30 mg/L Mg, or 125 mg/L if the sulfate concentration is < 250 mg/L and the chloride concentration is < 200 mg/L. In the EEC regulation 80/778 EWG the limit for drinking water is 50 mg/L Mg and 25 mg/L Cl^-. In the dehydration of magnesium chloride hydrates, hydrogen chloride occurs in the waste gases due to partial decomposition to magnesium oxide and the concentration must be kept below the permitted limit by use of gas purification equipment. The German TA Luft Regulations specify a maximum of 30 mg/m^3 HCl in air. Limits in Australia are 200 – 400, in the United Kingdom 150, and in Japan 80 – 700 mg/m^3.

3.5. Quality Specifications and Analysis

Quality Specifications. Magnesium chloride is available commercially in the form of solutions or solid hydrates. Solutions usually have a $MgCl_2$ content of 32 – 33 wt %. A typical solution with a $MgCl_2$ content of 32 – 33 wt % has the following approximate composition (in grams per liter);

$MgCl_2$	430 – 440
$MgSO_4$	12 – 25
KCl	2 – 3
NaCl	4 – 6
H_2O	ca. 870

For many applications, however, solutions produced by decomposition of carnallite (see Section 3.3.2) are used directly; due to transport costs this only applies when the user is close to the supplier.

The most important hydrate sold commercially is the hexahydrate (bischofite) which contains 43 – 47-wt % $MgCl_2$, ca. 51.5 wt % water,

ca. 2 wt % alkali metal chlorides, and, depending on its origin, some $MgSO_4$, $CaSO_4$, or $CaCl_2$. It is supplied in the form of broken pieces or flakes, or as blocks produced by melting and pouring into drums. Another hydrate in granular form contains ca. 2 – 3 mol of water per mole of $MgCl_2$ and corresponds to 67 wt % $MgCl_2$. Anhydrous magnesium chloride is mostly used directly by the producer for electrolytic magnesium production (→ Magnesium).

Analysis. For quality control the $MgCl_2$ solutions and the solid hydrates must be analyzed for the following ions: Mg^{2+}, Ca^{2+}, K^+, Na^+, Cl^-, SO_4^{2-}, and Br^-. In special cases, determination of boron, iron, and other ions may be required.

Magnesium and calcium are titrated complexometrically with ethylenediaminetetraacetic acid (EDTA) [36], [37]. Potassium and sodium are determined by flame photometry [38], or by ICP [39]. For the determination of sulfate ions, a titration with barium perchlorate solution in a 2-propanol–water mixture is carried out with thorin as the indicator [40] or it is analyzed by ICP. Bromide is determined gravimetrically by the method of D'Ans and Höfer [41].

The water content of the hydrates is determined by heating to 450 – 600 °C or by the lead oxide method [42]. Boron can be determined photometrically with azomethine-H or dianthrimide-1-amine [43], [44] and iron with bathophenanthroline (4,7-diphenyl-1,10-phenanthroline) [45]. Iron can also be determined by atomic absorption spectrophotometry [46] or by ICP.

3.6. Transportation and Storage

Magnesium chloride solutions can be transported in tank wagons. Owing to their corrosive properties, they should be stored in plastic containers reinforced with glass fiber, but iron vessels can also be used. When a 32 – 33-wt % $MgCl_2$ solution is cooled, $MgCl_2$ hydrates precipitate, gradually forming a sludge. At – 33.6 °C the residual solution containing 21.4 wt % $MgCl_2$ freezes as a eutectic mixture. The hexahydrate is transported in polyethylene sacks or big bags capable of holding > 50 kg. It is also supplied in the form of broken pieces or solid blocks produced by pouring molten salt in single-journey steel drums. Sealed vessels can be stored almost indefinitely, but, after opening, the material must be used immediately because of its hygroscopicity. All containers must be stored under dry conditions.

3.7. Uses

Anhydrous magnesium chloride is used chiefly for the electrolytic production of magnesium metal (→ Magnesium). Large quantities of magnesium chloride solutions are used to produce anhydrous magnesium chloride for this purpose.

An important area of application for the hexahydrate and the hydrate containing 67 % $MgCl_2$ is in the production of Sorel cement. This is made by mixing magnesium oxide with $MgCl_2$ solutions, and is mainly used as a binder for industrial floorings on account of its high elasticity and bending tensile strength properties [47]. This binder is also used in the manufacture of abrasive materials and grindstones, and for cementing rock faces during coal mining operations [48]. In combination with wood chippings, it can be used to make lightweight building slabs. Sorel cement mixtures are also used in water- and fire-resistant building materials [49]. They also serve as a binder for granulated fertilizers and in the production of salt licks for animals, where the magnesium also acts as a feed additive, preventing diseases such as grass tetany in cattle that are caused by magnesium deficiency [50].

Another application for $MgCl_2$ solutions and the hexahydrate is the manufacture of sintered magnesia and very pure $Mg(OH)_2$ (see Section 4.2.5). A high proportion of the solutions produced in Israel and the Netherlands are used for this purpose. Magnesium chloride hexahydrate and potassium chloride are used to produce artificial carnallite, which is used as a covering flux in the melting of light metal alloys. In the Quentin process used in the sugar industry, the alkali metal ions in the dilute sugar syrup are replaced by magnesium ions by treating it with an anion-exchange resin, thus reducing sugar losses in the molasses by improving sugar crystallization [51]. The resin is regenerated with $MgCl_2$ solution. In the mineral oil

industry, $MgCl_2$ solutions are used as drilling fluids in rocks with a high salt content. The low freezing point of the 21 % $MgCl_2$ solution ($< -30\,°C$) is utilized to prevent wet bulk materials from freezing to a solid mass. It is used as a de-icing agent in winter, as a ballast liquid for the tires of construction machinery and agricultural vehicles, for fire-extinguishing foams at low temperatures, and as brine for refrigeration. It is used in road surfaces combined with minerals and asphalt as a antifreeze. It is also used as a heat storage medium in solar heating installations, as an additive in the steel industry, as a coagulant in wastewater treatment, and in the treatment of combustion gases ($MgCl_2$ solution absorbs HCl and improves the removal of SO_2 by lime). In the plastics industry it is used in the manufacture of polymerization catalysts, e.g., in combination with $TiCl_4$ in Ziegler – Natta catalysts for the polymerization of $C_2 - C_{12}$ olefins. Addition of $MgCl_2$ also reduces losses of ammonia that is used as a fertilizer [52].

$MgCl_2$ is used in the production of moisture-proof salts. It is also used in the pharmaceutical and cosmetic industries, in food- and feedstuffs, and in bath salts. In addition it is used in the production of other Mg salts such as magnesium-chlorate.

3.8. Economic Aspects

The total worldwide production of $MgCl_2$ in 1996 was 1.5×10^6 t. In the world export markets ca. 300 000 t $MgCl_2$ was handled: ca. 200 000 t in the form of 33 % $MgCl_2$ solutions, and 100 000 t in the form of the hexahydrate. About half of the $MgCl_2$ solution was used for production of magnesium metal. In addition, approximately 180 000 t $MgCl_2$ from solution mining brines and 150 000 t $MgCl_2$ as 33 % solution were converted to magnesium oxide; these quantities were reported as material produced but not marketed. A further ca. 700 000 t magnesium chloride was not recorded in any statistics because it was used solely as an intermediate for the production of magnesium by electrolysis.

The most important countries for the production of $MgCl_2$ solutions and the hexahydrate are given below (excluding magnesium metal producers):

Germany (Kali und Salz AG)	byproduct solutions from the potash industry
Israel	Dead Sea brines
Netherlands	solution mining brines
Japan	sea bitterns from salt production
France	sea bitterns
United States	Great Salt Lake brines
Italy	sea bitterns
China	brines from various salt lakes
Australia	from Kunwarara magnesit deposit

Two thirds of the material appearing on the market originates from Germany.

3.9. Toxicology and Occupational Health

The handling of $MgCl_2$ hydrates, anhydrous $MgCl_2$, or $MgCl_2$ solutions on a laboratory scale does not present any personal hazards. German chemical regulations do not require any special marking. The LD_{50} (rat, oral) for $MgCl_2 \cdot 6\,H_2O$ is 8100 mg/kg. Eye protection and rubber gloves should be worn for handling anhydrous $MgCl_2$, $MgCl_2$ hydrates, or solutions. Prolonged contact with concentrated (ca. 35 wt %) solutions or with $MgCl_2$ dust can cause skin irritation, and possibly allergic skin reactions. In the event of skin problems, the affected area should be washed with copious soap and water, followed by treatment with a fat-containing skin cream. In case of contact with the eye, the eye should be washed with water and medical assistance should be obtained.

4. Magnesium Oxide and Hydroxide

Magnesium oxide [*1309-48-4*], MgO (magnesia, periclase), seldom occurs as a natural mineral; it is found in contact metamorphic limestone and dolomite, in volcanic ejecta, and in serpentine rocks. It does not form rocks or salt deposits because it is converted to magnesium hydroxide by the water vapor in the atmosphere. The primary sources of industrially produced magnesia are natural magnesite ($MgCO_3$), seawater, and natural and synthetic brines. Magnesium hydroxide is formed as an intermediate in the production of magnesia from seawater and brines. Magnesia is used in technical applications on account of its high melting point, chem-

ical resistance, high thermal conductivity, low electrical conductivity, and biological activity.

Technical-grade magnesia is mainly sintered to form *sintered magnesia* (also known as magnesia sinter, dead-burned magnesia, or sintered magnesite) which is used primarily as a refractory material and in the steel industry. Large quantities of calcined (decarbonated) material known as *caustic magnesia* or caustic-calcined magnesia, are produced for use in agriculture and the building industry. *Fused magnesia* is normally produced by melting caustic magnesia.

Magnesium hydroxide [*1309-42-8*], $Mg(OH)_2$ (brucite) is produced by precipitation of seawater and brines with calcium hydroxide (Section 4.2.2) or by precipitation of soluble magnesium salts. Natural deposits are rare and are not currently being mined.

4.1. Properties

Magnesium oxide [*1309-48-4*], MgO (magnesia, periclase [55]), M_r 40.31, is stable in an oxidizing atmosphere up to ca. 2300 °C and up to ca. 1700 °C in a reducing atmosphere.

Crystal Structure. Magnesia forms colorless, green, or brown, cubic hexoctahedral crystals, space group $O_h^5 - Fm\,3m$, ionic radius of Mg^{2+} 0.078 nm, $a = 0.421$ nm, $Z = 4$, cleavage parallel to (100).

Physical Properties

mp	ca. 2800 °C
Mohs hardness	5.5 – 6
Density	3.58 g/cm^3
Refractive index at 589 nm	1.736
Enthalpy of formation (298 K)	− 14 900 kJ/kg
Specific heat c_p	
20 – 200 °C	1.0 kJ kg^{-1} K^{-1}
20 – 1000 °C	1.2 kJ kg^{-1} K^{-1}

1300 °C	1×10^{5} Ω · cm

Magnesium hydroxide [*1309-42-8*], $Mg(OH)_2$ (brucite), M_r 58.33, starts to decompose at 380 °C.

Crystal Structure. Magnesium hydroxide forms ditrigonal scalenohedral crystals with a typical layer structure, space group $D_{3d}^3 - P\,\bar{3}m\,1$, $a = 0.313$ nm, $c = 0.474$ nm, $Z = 1$, cleavage parallel to (0001).

Physical Properties

Mohs hardness	2.5
Density	2.38 g/cm^3
Refractive index	n_ε 1.566, n_ε 1.581
Enthalpy of formation (298 K)	−15 800 kJ/kg
Dissociation energy (298 K)	+570 kJ/kg
Hydration energy	−386 kJ/kg
Solubility in cold water	0.0009 wt %

Toxicity. Magnesium oxide and hydroxide are not toxic. Precautions for handling dust must be observed when products with a small particle size are used.

4.2. Production of Magnesium Oxide

Caustic and sintered magnesia are generally obtained from magnesium carbonate or magnesium hydroxide. The production of the latter starting materials is described in Sections 4.2.1, 4.2.2, 4.2.3, 4.2.4. The burning and sintering processes are dealt with in Section 4.2.5. The production, properties, and uses of fused magnesia are described in Section 4.5.

4.2.1. Production from Magnesite [56]

The production of magnesium oxide from magnesite began over 100 years ago in Austria, after the development of processes for the manufacture of steel from high-phosphorus pig

iron in crucibles lined with sintered dolomite ($CaO \cdot MgO$).

Occurrence of Magnesite. Magnesia is produced from macro- and cryptocrystalline magnesite. Metamorphic *macrocrystalline magnesite* occurs in two Alpine mountain chains in varying degrees of purity. The rocks mainly consist of the isomorphous carbonate mineral $(Mg, Fe)CO_3$ (breunnerite), whose calcination results in the inclusion of 1 – 10 % Fe_2O_3 in the periclase lattice. In addition, they contain small amounts of dolomite ($CaCO_3 \cdot MgCO_3$), calcite ($CaCO_3$), phyllosilicates (e.g., talc, mica, chlorites, or clay minerals), graphitic particles, and sometimes quartz. Similar magnesite deposits are exploited in the former Czechoslovakia, in the Pyrenees, in Ural (Satka), South Manchuria (Liaoning), East Brazil, and Canada, both by open-cast and underground mining. The macrocrystalline rocks are always subjected to some form of processing before calcination.

In contrast to the macrocrystalline magnesites, which form extensive or lenticular deposits, *cryptocrystalline magnesite* deposits are irregular and often veined. The rocks are mostly snow white, even if they are not composed of high-purity $MgCO_3$. They are regarded as being formed by the alteration of ultrabasic rocks (e.g., serpentines) through the action of water containing carbon dioxide. Deposits of this type occur in former Yugoslavia, Greece (Chalkidike and Euboa), Turkey, India, Nepal, and South Africa. They contain chalcedony (finely divided SiO_2), various magnesium silicates, and dolomite as accompanying minerals. The deposits are exploited mainly by open-cast mining, but also by underground mining.

Sedimentary deposits of cryptocrystalline magnesite have been identified in the last 20 years. They are often associated with deposits of hydromagnesite and huntite. The sedimentary deposits are formed in semi-arid basins associated with strongly weathered ultrabasic rocks. The material washed into the basin dissolved and then recrystallized on the basin rim, mostly in the form of porous concretions. A more recent formation of this type has been found in Southwest Turkey [57], while an older deposit has been reported in North Greece [58], [59]. A large deposit of this type was discovered in Australia (Kunwarara) in 1985. The Queensland magnesia project has been planned for the production of sintered and fused magnesia [60], [61].

Magnesite Beneficiation. The insufficient purity of the magnesite and the stringent specifications for the uniformity of sintered magnesia mean that beneficiation of the magnesite is usually necessary. The steps used in the beneficiation process depend on the ore being processed and the required carbonate purity.

The highest quality magnesites, particularly those for refractory applications, are needed for a magnesia product with a high MgO content, a $CaO : SiO_2$ mass ratio of 2 – 3, and low contents of Fe_2O_3 and Al_2O_3. The presence of accompanying, low-melting minerals can adversely affect the properties of the sintered magnesia (cf. Table 2).

Preliminary sorting of the ore can be achieved by *selective mining*. The ore is then subjected to *selective coarse grinding* in impact crushers. The tailings can be separated from the ore by taking advantage of the difference in hardness; the ore is selectively crushed and removed by screening. Crushing is usually performed in several stages. The final particle size for calcination in shaft kilns is 20 – 200 mm, while a particle size of 2 – 60 mm is required for the more commonly used rotary kilns.

The difference in color between the cryptocrystalline magnesite ore and the tailings is usually so pronounced that *sorting* can be carried out by hand on a conveyor belt or with an automatic optical system.

The coarsely ground material is often *washed* and subjected to *wet desliming* to remove fine particles. Ore that is intended for direct caustic calcination is separated from fine material (often lamellar silicate particles) by screening.

When the magnesite is not intimately intergrown with its accompanying minerals, lump material for rotary kilns can be sorted by *gravity separation*. This is carried out in one or two stages in a dense-medium separator or cyclone to give particles of sizes of 10 – 40 or 4 – 60 mm, respectively. Since the differences in density are small (magnesite 2.95 – 3.05, dolomite 2.90, calcite 2.70, lamellar silicates 2.5 – 2.95, quartz 2.65, graphite 2.1 – 2.2 g/cm^3), separation depends on exact control of the density. Finely divided ferrosilicon is generally used as the dense medium; the impurities are removed

Table 2. Minerals accompanying periclase in sintered magnesia

Mineral	Formula	Abbreviation [a]	C: S [b]	*mp*, °C
Forsterite [*15118-03-3*]	$2\,MgO \cdot SiO_2$	M_2S	0	1890
Monticellite [*14567-83-0*]	$CaO \cdot MgO \cdot SiO_2$	CMS	0.94	1495
Merwinite [*13596-18-4*]	$3\,CaO \cdot MgO \cdot 2\,SiO_2$	C_3MS_2	1.40	1575 (decomp.)

[b] Mass ratio of CaO to SiO_2 (dissolution of small amounts of CaO in the MgO is neglected).
[c] Several modifications.

as floats. The throughput in modern plants is 50 – 150 t/h.

If the degree of intergrowth of the magnesite with its accessories lies in the range 0.03 – 1 mm, separation can only be achieved after thorough grinding of the ore (particle size below ca. 0.2 mm) to expose the accompanying minerals. The most effective separation and enrichment process for this material is *flotation*, which exploits the differing wettabilities of the various minerals (→ Flotation). The process must be optimized for each deposit.

The magnesite is finely ground in rod or ball mills and should have as narrow a particle size distribution as possible (ca. 0.09 mm for coarsely crystalline magnesite). This is achieved by combining milling with gravity classification and classification cyclones. Flotation is usually preceded by desliming to remove the finest particles, which would otherwise cause problems in the flotation step.

The removal of talc, $Mg_3(OH)_2Si_4O_{10}$, is straightforward. Upon mixing with air in the presence of weak collectors – frothers (e.g., pine oil and primary aliphatic fatty amines), the talc particles float to the surface on bubbles and are removed by skimming.

The main problem in flotation is the separation of magnesite from dolomite, calcite, and silicates other than talc. Separation is achieved by *direct magnesite flotation* which entails the use of nonspecific, anionic collecting agents (that also act as frothers) and selective depressing agents for dolomite, calcite, and silicates. The flotation cells have a capacity of 0.5 – 3 m^3. The operational conditions in the flotation cells must be optimized (temperature, pH value, reagent dosing). In large-scale flotation plants, several series of cells are run in parallel. The typical throughput of a series is 20 t/h of magnesite, corresponding to 60 m^3 of suspension with a density of 1.25 g/cm^3. The magnesite concentrate is removed as a foam, then thickened, and brought to a residual water content of 8 – 12 % in centrifuges or filters. The product is then briquetted and burned (see Section 4.2.5). The waste slurries from the desliming and flotation stages are treated in thickeners, filters, and settling basins.

An important sorting process for high-iron sintered magnesia is *magnetic separation* (→ Magnetic Separation). The isomorphic inclusions of iron in the magnesite crystal cannot be removed by mechanical separation. After sintering and subsequent cooling, they are converted to magnetic magnesioferrite ($MgO \cdot Fe_2O_3$), either in the periclase lattice or at its crystal boundaries (see Fig. 3B). Calcite and dolomite usually do not contain iron in the carbonate lattice; the calcination of large crystals gives large pieces of very pure, usually only lightly sintered, nonmagnetic CaO or CaO and MgO. These oxides can be separated, together with nonmagnetic silicates, from the sintered iron-rich magnesia in magnetic drum separators.

Recently developed magnets are reported to be able to remove pieces of sintered magnesia with a somewhat higher iron content from low-iron sinter [60].

Table 3 lists typical analyses of sintered magnesia produced from natural magnesite (types 1 – 4, 7).

4.2.2. Production from Seawater [62], [63]

Few deposits of pure or easily accessible magnesite were known up to the mid-1980 s. In the

** According to DIN 51 065, part 2.

1960s the increasing demand for sintered magnesia as a refractory lining material in the steel industry stimulated new developments in methods for production of magnesia from seawater. This method was first introduced on a small scale in 1865 on the French Mediterranean coast. Since the 1930s it has been employed on a large scale in the United States and England (Hartlepool).

The composition of seawater is given in Table 4 [64]. Calculations show that 470 m^3 of seawater are required to produce 1 t of MgO, in practice 600 m^3 are needed. The process is based on the precipitation of magnesium hydroxide (solubility in water 0.0009 wt %) by addition of calcium hydroxide (solubility 0.185 wt %):

$$Mg^{2+} + 2\,Cl^- + Ca(OH)_2 \longrightarrow Mg(OH)_2\downarrow + Ca^{2+} + 2\,Cl^-$$

Freshwater from rivers contaminated with suspended material must not flow into the seawater used for magnesia production. Furthermore, the seawater to be extracted should not be mixed with already extracted seawater, this requires a suitable topography and tidal currents that run parallel to the coast. A supply of freshwater (>40 m^3 per tonne MgO) is required to wash the $Mg(OH)_2$ and to produce the milk of lime. High-purity limestone or dolomite deposits should be available in the vicinity; they are calcined and slaked to provide $Ca(OH)_2$ as the precipitating agent and should therefore contain minimal quantities of elements that form insoluble carbonates, sulfates, etc. The $MgCO_3$ in dolomite is converted to $Mg(OH)_2$, and thus provides a further source of magnesia.

Production of Precipitating Agent. The limestone or dolomite is thoroughly washed, crushed, and calcined at >1400 °C in a rotary or shaft kiln. The $CaCO_3$ must be completely decarbonated to CaO (<0.2 % CO_2), but should be lightly burned, and should contain minimal amounts of sulfur and other contaminants. In order to achieve rapid, complete reaction of the seawater, the calcined lime (quicklime) or dolomite (dolime) is ground, slaked to form $Ca(OH)_2$ and then converted into milk of lime or dolomitic slaked lime (containing ca. 20 % solids).

The seawater is pumped to the plant and suspended material is removed. Seawater contains dissolved carbon dioxide and must therefore be

Table 4. Composition of seawater [64]

Cation	Concentration		Anion	Concentration	
	g/kg	mmol/kg		g/kg	mmol/kg
Sodium	10.47	455.0	chloride	18.97	535.1
Potassium	0.38	9.7	bromide	0.065	0.81
Magnesium	1.28	52.5	sulfate	2.65	27.6
Calcium	0.41	10.2	bicarbonate	0.14	2.35
Strontium	0.013	0.15	borate	0.027	0.44

treated with sulfuric acid to prevent the subsequent formation of insoluble calcium carbonate on addition of $Ca(OH)_2$:

$$Ca(HCO_3)_2 + H_2SO_4 \xrightarrow{pH4} CaSO_4\downarrow + 2\,H_2O + 2\,CO_2$$

The freshwater is also partially decarbonated.

To ensure maximum removal of carbon dioxide, the water is pumped through a trickling installation into the reactor containing the milk of lime. The water leaving the reactor is pumped back into the sea; it has a low magnesium content, a high calcium content, and a pH of 10.5. In modern plants using the overliming process (see below), the extracted water is first pumped into settling basins where the excess lime is diluted with fresh seawater to precipitate more $Mg(OH)_2$ and to lower the pH to more ecologically acceptable values.

*Precipitation.*The aqueous suspension of finely precipitated $Mg(OH)_2$ is seeded with larger $Mg(OH)_2$ crystals in large, flat settling tanks to convert it into a thick, dense slurry for filtering. The slurry is removed from the bottom of the tank and fed into tanks where it is washed with decarbonated seawater and decarbonated fresh water to remove most of the alkali metal, chloride, and other ions. The water content of the $Mg(OH)_2$ slurry is then reduced to $< 50\,\%$ by filtration (vacuum disk or drum filter). The product is used as a starting material for caustic and sintered magnesia (see Section 4.2.5).

Unless specially treated, caustic and sintered magnesia produced from seawater usually contain ca. 0.2 % B_2O_3 and small amounts of CaO, SiO_2, Al_2O_3, and Fe_2O_3 derived from the limestone or wastes in the seawater. The contaminants and the $CaO{:}SiO_2$ (C:S) ratio have a pronounced effect on the behavior of the magnesia during sintering and in its subsequent applications. The C:S ratio is therefore adjusted to the desired value (3 – 4 or more for the high-quality sinters used in oxygen metallurgy). The B_2O_3 content of the magnesia is also generally lowered to ca. 0.05 % by using a 5 – 12 % excess of lime for precipitation (overliming); this increases the pH to 12 and minimizes the adsorption of boron. Addition of small quantities of Na_2CO_3 prior to sintering further decreases the B_2O_3 content to 0.03 % due to the formation of volatile sodium borate during sintering. Prolonged sintering at the maximum temperature decreases the B_2O_3 content. Ion exchange can also be used to lower the boron content of the seawater and thus of the sintered product.

Typical compositions of the two most common types of magnesia sinter derived from seawater are given in Table 3 (types 5 and 6).

4.2.3. Production from Brines

Precipitation of Magnesium Hydroxide. Large marine and terrestrial salt deposits were formed in various geological periods. Fossil mineral salt deposits have been mainly mined for their potassium salts: magnesium salts or magnesium brines are obtained as waste or as a byproduct.

Magnesium salts are formed in arid areas by evaporation of brines in flat basins, their composition often differs from those obtained from seawater. Magnesia is obtained from magnesium (potassium) brines of varying origin:

1) Synthetic brines produced during solution mining (e.g., Veendam, Netherlands)
2) Spent liquors obtained in salt production from natural brines (e.g., Dead Sea, potash

production; Laguma de Rey, Mexico, sodium sulfate production)
3) Spent liquors obtained in salt production from salt deposits (e.g., Teutschenthal, Germany)

In the Netherlands (Veendam, Ost-Groningen), purified freshwater is forced into an anticline at a depth of 1500 m to dissolve the bischofite ($MgCl_2 \cdot 6\ H_2O$) and carnallite ($KCl \cdot MgCl_2 \cdot 6\ H_2O$) [65]. The brine is then pumped to the surface and contains 20 wt % $MgCl_2$ and small amounts of alkali chlorides and $MgSO_4$. After removal of the sulfate, the magnesium is precipitated as $Mg(OH)_2$ with dolomitic slaked lime (see Section 4.2.1), thickened, and then sintered. The advantage of this deposit is that the bicarbonate and boron contents of the resulting brines are much lower than those of seawater and do not have to be removed by complex methods.

Pyrohydrolysis of Magnesium Chloride [66], [67]. In pyrohydrolysis, metal (M) halides (especially chlorides) are thermally decomposed in the presence of superheated steam at 300–1000 °C to give a pure, fine metal oxide precipitate:

$$M(II)Cl_2 + n\ H_2O \rightarrow MO + 2\ HCl + (n-1)H_2O$$

Pyrohydrolysis was originally used to recover hydrochloric acid in the pickling of steel but it can also be employed for the large-scale production of metal oxides. Magnesium oxide is produced from natural or synthetic $MgCl_2$ brines. Complete hydrolysis of $MgCl_2$ by conventional methods is not possible because evaporation leads to precipitation of bischofite ($MgCl_2 \cdot 6\ H_2O$) which, on further heating, melts or dissolves in its own water of crystallization. Complete pyrohydrolysis of $MgCl_2$ is achieved in a spray reactor without hydrolysis of $CaCl_2$ and alkali chlorides (Aman process).

The *Aman process* has been used since 1973 in an industrial plant with a capacity of 70 000 t/a near the Dead Sea. The starting material for this process is the spent liquor (brine) obtained after extraction of KCl from a magnesium- and alkali-chloride-rich natural brine. The compositions of these brines are given in Table 5.

The brine is purified to remove bromide and traces of boron and then fed via steel pipes into the spray nozzles of the reactor. It is sprayed into the cylindrical, externally insulated reactor at ca. 600 °C. The reactor is lined with refractories, it also has a conical base and tangentially positioned burners which ensure rotating circulation of the reactants. The exhaust gases leave the top of the reactor at 450 °C. The water evaporates from the atomized brine droplets leaving a perforated chloride crust which reacts with the steam to form MgO and HCl. The hollow spherical MgO agglomerates are removed from the bottom of the reactor via a gas lock, together with nonpyrolyzed, water-soluble potassium, sodium, and calcium salts.

Table 5. Composition (in grams per liter) of brines used in the production of magnesia by the spray roasting method

Component	Natural brine	Brine for pyrohydrolysis after KCl extraction
Mg^{2+}	41	102
Na^{+}	40	2
Ca^{2+}	17	9
K^{+}	7.5	2
Cl^{-}	215	319
Br^{-}	5	6
SO_4^{2-}	0.7	
Total	326	440
$MgCl_2$	163	400

The crude product is washed with water and hydrated in a stirred tank, and then concentrated in a thickener. The resulting slurry is difficult to filter and is washed and dewatered in a two-stage vacuum drum filter. The calcined product typically contains ≥ 99.5 wt % MgO, < 1 wt % CaO, ≤ 0.05 wt % SiO_2, ≤ 0.05 wt % Fe_2O_3, ≤ 0.005 wt % Al_2O_3, and ≤ 0.01 % B_2O_3; its specific surface area is 2–50 m^2/g, the loose bulk density ranges from 0.8 to 0.2 g/cm^3.

Most of the MgO dust in the hydrogen chloride exhaust gas is removed with a cyclone. The hot gas is then used to heat the fresh $MgCl_2$ solution in a wash recuperator where any remaining MgO dust is collected. The HCl gas is scrubbed with water in an absorption column. After removal of the combustion gases and steam, 20 % hydrochloric acid is obtained which is used to dissolve local phosphate deposits; this makes the process economically viable.

Pyrohydrolysis of Magnesium-Containing Waste. The principle of the above method can

also be used for the pyrohydrolysis of chloride solutions obtained from impure magnesium minerals such as magnesite, tailings, dust, asbestos, talc, and other magnesium silicate waste [68]. The hydrochloric acid byproduct is recycled within the process (former Yugoslavia, Nepal, Austria, and Germany).

The magnesium is dissolved with hydrochloric acid in a two-stage process. Neutralizing agents (filter dust or crude MgO), oxidizing agents (air, chlorine gas), and sulfate ions are then added. Heavy-metal hydroxides, calcium sulfate, and other contaminants precipitate out and are filtered off to leave a $MgCl_2$ solution that is concentrated in a vacuum evaporator and sprayed into the reactor.

4.2.4. Miscellaneous Processes

Sulmag II Process [69]. The Sulmag II process was developed by Sulzer for producing light-burned caustic magnesia in a gas suspension kiln from low-magnesite ores. Dissolved magnesium chloride is obtained by selective extraction with recycled NH_4Cl solution:

$$2\,NH_4Cl + MgO + H_2O + \text{Contaminants} \longrightarrow 2\,NH_4OH + MgCl_2 + \text{Tailings}$$

After filtration and washing, needle-shaped crystals of nesquehonite are precipitated out in the reactor and filtered off:

$$MgCl_2 + (NH_4)_2CO_3 + 3\,H_2O \longrightarrow MgCO_3 \cdot 3\,H_2O\downarrow + 2\,NH_4Cl$$

Caustic magnesia with a high specific surface area is obtained by directly heating the nesquehonite with oil or gas and briquetting while still hot. The product is then sintered. This process is reported to produce significant energy savings and is environmentally favorable due to the almost complete recycling. A pilot plant has been in operation in Switzerland for several years and a plant designed to produce 30 000 t/a of sintered magnesia is under construction for Tamilnadu Magnesite in India.

Other Processes. Processes have been described in which dolomite is decarbonated to form a mixture of CaO and MgO and the CaO is then chemically extracted. Patents also describe the partial decarbonation of dolomite, slaking of the MgO, and recarbonation. The product consists of large nesquehonite crystals ($MgCO_3 \cdot 3\,H_2O$) which are separated from the microcrystalline $CaCO_3$ by flotation. The accessory calcite and dolomite can also be extracted from magnesite rocks because they are readily soluble in acid.

Figure 3. Polished sections of sintered dolomite (A), sintered magnesia (B – G), and fused magnesia (H)
A) Sintered dolomite: white areas are MgO, gray areas CaO, and black areas pores; B) High-iron magnesia sintered in lumps: white domains are $2\,CaO \cdot Fe_2O_3$ and $MgO \cdot Fe_2O_3$, dark gray areas are pores that run parallel to the carbonate cleavage planes (type 4 in Table 3); C) Briquetted high-iron sintered magnesia with a high porosity (type 2 in Table 3); D) Low-iron magnesia sintered in lumps (type 7 in Table 3); E) Seawater magnesia "31" (type 6 in Table 3); F) Sintered magnesia from brine (type 9 in Table 3); G) Low-iron C sintered magnesia (type 8 in Table 3); H) Fused magnesia with periclase cleavage planes

Magnesia can also be prepared from Epsom salt ($MgSO_4 \cdot 7\ H_2O$) or kieserite ($MgSO_4 \cdot H_2O$) but this technique is not used industrially at present.

Figure 4. Differential thermal curves for $Mg(OH)_2$ (A), $MgCO_3$ (B), and $MgCO_3 \cdot 3\,H_2O$ (C) [85]

MgO and CaO Production by Sintering of Dolomite. Complete decarbonation of dolomite theoretically leaves a finely crystalline mixture of MgO (42 %) and CaO (58 %).

Since large supplies of natural, high-purity dolomitic rocks are available, removal of contaminants by beneficiation is not economical. The high-purity lump dolomite is calcined, and sintered in a rotary or shaft kiln. In a special procedure the dolomite is decarbonated, briquetted, and sintered at a lower temperature than the lump material to give a high-density product. The CaO and MgO crystals in sintered dolomite lie directly adjacent to one another (Fig. 3A); despite the intense burning they are much smaller than those of sintered magnesia because they mutually hinder one another's crystal growth.

4.2.5. Burning of Caustic and Sintered Magnesia

Caustic magnesia is a very reactive, finely crystalline material that is produced by burning $MgCO_3$ or $Mg(OH)_2$ slightly above the decomposition temperature. The decomposition curves for $Mg(OH)_2$, $MgCO_3$, and $MgCO_3 \cdot 3\,H_2O$ are shown in Figure 4. Caustic magnesia may be the end product of magnesia production (for uses, see Section 4.3.3) or may be further burned to give sintered magnesia.

Caustic magnesia is produced industrially by calcining lump $MgCO_3$ (up to 50 mm) or finer material at 600 – 1000 °C in shaft, rotary, or multiple-hearth (Herreshoff) kilns. Heat-exchange kilns are also employed. In the case of $Mg(OH)_2$, dewatered filter cakes are usually calcined in lump form at ca. 950 °C in multiple-hearth kilns. These kilns generally contain ten shelves (hearths), one above the other; each hearth is provided with four burners in the vertical cylindrical kiln wall. The material is fed continuously into the top of the kiln and its residence time can be adjusted via the rake that rotates above each hearth. The calcining conditions must be carefully adapted to the contaminants in the feed, otherwise overburning results in excessive growth of the reactive MgO crystallites which lowers their activity. In modern gas suspension furnaces, $Mg(OH)_2$ or flotation concentrate can be converted into homogeneous caustic magnesia; energy consumption is low [70].

Caustic magnesia was formerly produced exclusively from cryptocrystalline magnesite with a low iron content but is now also obtained from all types of magnesite and $Mg(OH)_2$. Its MgO content ranges from ca. 65 to 99 wt %, and may

even reach 99.9 %. The magnesia is often ground prior to use. Extremely reactive caustic magnesia may have a surface area of up to 160 m^2/g.

Depending on the burning temperature, the product is termed *light burned* (870 – 1000 °C) or *hard burned* (1550 – 1650 °C). Light-burned caustic magnesia becomes hydrated in cold water and is soluble in dilute acid. It has a loose bulk density of 0.3 – 0.5 g/cm^3 and a specific surface area (BET) of 10 – 65 m^2/g. Hard-burned caustic magnesia has a loose bulk density of 1.2 g/cm^3 (bulk density 2 g/cm^3).

Sintered Magnesia. Most (ca. 85 %) $MgCO_3$ and $Mg(OH)_2$ is converted into sintered magnesia (also known as magnesia clinker or dead-burned magnesia, Fig. 3B – G). Typical analyses and densities of sintered magnesia are given in Table 3). Uses are described in Sections 4.3.1 and 4.3.2. Sinter quality depends not only on chemical composition but also on the bulk density or porosity; a high density gives a better product. Sintering capability decreases considerably with increasing purity, making a high density difficult to achieve. In the early 1960s lump magnesite with a low iron content could not even be sintered to a density of 3.40 g/cm^3 (porosity ca. 5 vol %). Although some briquetted, low-iron, C_2S-containing sinters have densities of up to 3.46 g/cm^3 (porosity ca. 3.5 vol %), the density is usually in the range 3.35 – 3.40 g/cm^3. The final bulk density of the sinter depends on chemical composition, sintering temperature and time, and the degree of compression of the material prior to sintering (briquetting is therefore used and not pelletizing or granulation). The material is usually sintered in lump form.

Caustic magnesia (preferably hot, 200 – 500 °C) is compressed into briquettes on high-pressure roller presses (pressure 4 – 15 t/cm). The briquettes are then screened and dried or hardened. The screened fines are mixed with fresh caustic magnesia and briquetted.

Binding and adhesive agents are added to fine *magnesite flotation concentrates* prior to briquetting; magnesium sulfate solution, sulfuric acid, lignin sulfonates, and reactive MgO flue dust are usually used. Magnesite concentrates are also used to produce double-burned sinter. Here the concentrates are first calcined to reduce the mass and the resulting gas pressure; they are then briquetted and sintered.

In some cases dewatering of *magnesium hydroxide slurries* is so efficient (high-performance filter presses) that pieces of the hard filter cake can be fed directly into a rotary kiln. This saves a considerable amount of energy and the sintered magnesia product usually has a sufficiently high bulk density. In most modern plants, however, the hydroxide slurry is first calcined and then briquetted.

Shaft kilns are heated with coke, gas, or oil (with or without oxygen) and must be fed with large pieces of material due to the pattern of gas circulation and movement of material within the shaft. Today, shaft furnaces can be better controlled than was the case a few years ago [71]. Smaller lumps (0.5 – 60 mm, product 0 – 30 mm) are used in rotary kilns to minimize abrasion and guarantee even movement of the material from the rotating kiln wall. Rotary kilns are generally oil- or gas-fired, sometimes with addition of coal dust or petroleum coke. Depending on the content of fluxing agents, sintering is performed at 1700 to > 2000 °C for 2 – 15 h (rotary kiln) or ca. 20 h (shaft kiln). The sinter from rotary kilns is generally homogeneous but has a smaller particle size and contains more dust than that from shaft kilns; this can lead to undesirable, round particles and an excess of fines during brick production. Cryptocrystalline magnesite with a low content of fluxing agents gives a sinter with a needle-like structure also after sintering in a rotary kiln.

Energy consumption for the burning of high-quality sintered magnesia from various starting materials depends on kiln design and the water content of the $Mg(OH)_2$ slurry; typical values are as follows (MJ/kg MgO):

Magnesite: single-stage burning (magnesite → sinter)	4.5 – 12
Magnesite: double-stage burning (magnesite → caustic magnesia → sinter)	8 – 16
Seawater magnesia [$Mg(OH)_2$ → caustic magnesia → sinter, value includes energy required for production of precipitation agent]	22 – 32
Sulmag II process	23
Magnesia produced by pyrohydrolysis	40

In an effort to improve sinter quality, manufacturers first turned their attention to increasing the size of the periclase crystallites by adding sinter-promoting agents, such as ZrO_2. Burning conditions were subsequently modified. In larger crystallites the MgO is less easily reduced by carbon at high temperatures (e.g., in magnesia – graphite bricks; see also Fig. 3G).

Modification of Sinter Composition. In the case of concentrates, slurries, or caustic magnesia, the final composition of the sinter can be modified by mixing in small amounts of additives such as CaO, SiO_2, and Fe_2O_3 prior to briquetting. Magnesite concentrates obtained by flotation and fine $Mg(OH)_2$ or MgO can also be mixed with large quantities of other fine substances (primarily chromium ores, calcined lime or dolomite), briquetted, and sintered to form coclinker. In refractory bricks made from pure sintered magnesia and low-silicate chromium ores, the chromium ore only becomes fully integrated with the periclase at high temperature ($\geq$ 1700 °C) and in a suitable atmosphere. In briquettes made from magnesia and fine chromium ore, however, sintering results in complete dissolution of the mixed spinels of the ore in the periclase. On cooling, fine crystalline spinels or skeleton crystals precipitate in the periclase; some idiomorphic spinels (Mg, Fe^{2+})O (Cr, Fe^{3+}, Al)$_2O_3$ are evenly deposited between the periclase crystallites.

4.3. Uses

The use of magnesium oxide and hydroxide as intermediates in the production of magnesium metal is described elsewhere (→ Magnesium).

4.3.1. Use of Sintered Magnesia as a Refractory

Oxides are best suited as "vessel linings" for most industrial high-temperature processes. Magnesium oxide has the highest melting point of the moderately priced oxides and is therefore an important raw material for refractory bricks and other materials (→ Refractory Ceramics). It is the only material apart from ZrO_2 that can withstand long-term heating above 2000 °C. Refractory construction materials based on magnesia (with chromium ore or CaO) are also resistant to neutral and basic slags and gases.

The boom in the production of low-iron sintered magnesia occurred after it was discovered that the use of refractory magnesia linings in steelmaking vessels (open-hearth furnace, electric arc furnace, and basic oxygen furnaces) allowed phosphorus and sulfur to be removed in the basic slag.

Sintered magnesia is converted into fired bricks by techniques used for traditional ceramics. It is first broken up, ground, and classified. Batches (1 to > 2 t) of individual fractions are mixed with a temporary aqueous binder (e.g., lignin sulfonates) and pressed into bricks of the desired shape weighing up to ca. 35 kg. After drying, the bricks are usually fired at 1500 – 1800 °C in a tunnel kiln. They have a final porosity of 12 – 20 vol %.

Bricks (especially those that are to be used in basic oxygen furnaces) may then be *impregnated with pitch* to prevent the slag from infiltrating them and dissolving their surface. Fired magnesia bricks have a high thermal expansion coefficient and a relatively low thermal shock resistance, especially during periodic operation. Fired bricks made from sintered magnesia and chromium ore (or alumina or spinel) are more resistant to thermal shock.

A large proportion of the magnesia bricks are not fired (i.e., do not form a ceramic bond) but are *bonded with pitch or resin*. The individual particle fractions are mixed with hot pitch, compressed into bricks, and tempered at 200 – 500 °C. When the bricks are used, a coke structure is formed which makes them more elastic than the ceramic-bonded bricks. Addition of 5 – 20 % flake graphite increases heat transfer, lowers thermal expansion and attack by the slag, and improves thermal shock resistance. This development is applied in electric arc furnaces, converters, and metal ladles for secondary steelmaking processes. The low-oxygen atmosphere formed in these bricks during use can cause significant reduction of the magnesia. To prevent this, manufacturers have developed high-quality magnesia with larger periclase crystals and a low internal sinter surface area [72].

Chemically bonded bricks with chrome ore contain chemical bonding agents (e.g., Epsom salt, $MgSO_4 \cdot 7\ H_2O$) and are produced in the same way as fired magnesia bricks up until the

drying stage. The bonding agents decompose and form a ceramic when the bricks are used at high temperature.

Pig iron mixers, transport vessels, and secondary refining ladles used in the steel industry are lined with magnesia bricks. Sliding gates and nozzles are also made from sintered magnesia.

On account of their high refractoriness (refractoriness under load and low creep in compression), resistance to alkali, and high heat storage capacity, magnesia bricks are used in the crowns, port linings, and the hot parts of the checkerwork in glass-melting tanks. Magnesia–chrome or magnesia–spinel bricks are more suitable for the sintering zones of rotary cement kilns due to their good stress deformation behavior. Magnesia bricks are preferred for lime shaft kilns. Large quantities of sintered magnesia are used for unshaped repair materials.

The increased demands made on refractory materials as a result of higher operating temperatures and shorter tap to tap times in metallurgical furnaces and reactors can only be met by pure, high-density magnesia sinters. Small quantities of "contaminants" are disadvantageous if they form low-melting eutectics with MgO (e.g., with CMS at 1485 °C or with C_2F at 1200 °C, Table 2) because this leads to deterioration of mechanical properties (e.g., strength and volume stability) at high temperatures. High-quality sinters therefore have a low content of high-melting silicate phases (such as C_2S), a low B_2O_3 content, and a high degree of direct periclase–periclase contact (without intermediate silicate phases).

4.3.2. Use of Sintered Magnesia as a Heat-Storage Medium

Magnesia bricks have a high heat storage capacity (about 160 % that of chamotte) and a high thermal conductivity [73]. They are used in efficient off-peak storage heaters. The heat generated by a heating element is transferred to the magnesia brick and increases its temperature.

The most suitable bricks are fired and have the following properties: a high bulk density (up to 3.10 g/cm^3) and thus a high degree of sintering, a high thermal conductivity (up to 9 W m^{-1} K^{-1} at 600 °C), and a high specific heat (1.1 kJ kg^{-1} K^{-1} at 600 °C). The influence of impurities on these factors is not as critical as in refractories.

The bulk density depends on the chemical composition, the sinter porosity and the method used to produce the bricks. Thermal conductivity is increased by a high periclase content and a low porosity. The specific heat is only slightly lowered by SiO_2 and Al_2O_3, but is significantly lowered by CaO, Cr_2O_3, and Fe_2O_3. The bricks should not contain free CaO (risk of hydration) or crystal phases with different modifications.

4.3.3. Uses of Caustic Magnesia

Agriculture. In the 1970 s and 1980 s the use of caustic magnesia increased the most in fertilizers and animal feeds [74–77]. Magnesium is a constituent of plant chlorophyll and also plays a role in enzyme activity. It is regarded as an essential plant nutrient and is used in *fertilizers* (→ Fertilizers). Magnesium deficiency (symptoms: chlorosis, necrosis) became especially common after fertilizers containing a high percentage of potassium replaced potassium–magnesium fertilizers based on kainite ($KCl \cdot MgSO_4 \cdot 3\ H_2O$). In countries with salt deposits (e.g., Germany), magnesium is supplied in the form of kieserite, magnesia lime (> 10 % MgO), and calcined dolomite. In all other countries (e.g., Netherlands, UK, USA), caustic magnesia (particle size 4 mm, ≥ 70 % MgO) and magnesite are used.

Ground caustic magnesia (particle size ≤ 2 mm, ≥ 85 % MgO) is used as a *supplement for animal feeds*. Magnesium is usually present in green fodder, but cattle and sheep feeding on fodder from slightly acid soils may suffer from "grass staggers" in spring which is caused by magnesium deficiency.

Building Industry. Caustic magnesia mixed with concentrated solutions of magnesium salts and a small amount of sodium phosphate becomes extremely hard and sets in air (e.g., with $MgCl_2$ solutions it forms $3\ MgO \cdot MgCl_2 \cdot 11\ H_2O$). However, the hardened material is not stable in water and is therefore not a true cement (which must set in air and water) but a *magnesia binder*. These binders were originally referred to as Sorel cement or as stonewood (xylolith) when mixed with sawdust as a filler. Since their

high chloride content can corrode metals and other construction materials, magnesia binders must never be reinforced. They can be used as mastics or protective coatings at room temperature. Large quantities of caustic magnesia derived from carbonate are used for stonewood or plaster flooring in the Eastern Bloc. The low-iron caustic magnesia generally used for this purpose contains 75 – 87 % MgO and is ground (40 –45 % < 10 μm).

An important use of caustic magnesia is in *lightweight construction boards* (Heraklith) for thermal and acoustic insulation (thickness 5 – 100 μm). The boards are produced on fully automatic lines at ca. 60 °C from finely ground caustic magnesia (MgO content 65 – 80 %, starting material magnesite containing silicates and dolomite), $MgSO_4$ solution as a binder, and impregnated pinewood chips. Mineral wool is also used as a filler. Subsequent hardening results in highly nonflammable boards which can be made fire-retardant and resistant to moisture and microorganisms by coating one side with plaster. The prefabricated boards are used to make formworks for concrete, and large quantities are used in combination with polystyrene in laminated boards.

Other Uses. Caustic magnesia containing ca. 70 – 99 % MgO is used in wastewater treatment, in prevention of corrosion, as a buffer, in preparative chemistry, and in the pharmaceutical industry.

Caustic magnesia can be used to remove heavy metals and silicate from wastewater. Ammonia can be precipitated and removed in the form of $Mg \cdot NH_4 \cdot PO_4 \cdot 6\,H_2O$ following addition of phosphoric acid and caustic magnesia [78]. The magnesium ammonium phosphate can be used as a fertilizer. This principle is also used to remove phosphate. Caustic magnesia is a mild base and neutralizes acids and acidic water, it also acts as a weak buffer.

Low-iron caustic magnesia is used as a filler in the plastics and rubber industries and allows adjustment of viscosity and stiffness. It also acts as a chlorine accepter in chlorinated hydrocarbon polymers and stabilizes them.

Large quantities of pure magnesium oxide are used in the chemical industry for the synthesis of magnesium compounds. Basic magnesium sulfonates and finely dispersed MgO are used as lubricant and motor fuel additives to neutralize combustion residues. Magnesium oxide in fuels binds sulfur and other compounds and prevents formation of acidic exhaust gases.

Large quantities of caustic magnesia are used in the paper and cellulose industries (magnesium bisulfite digestion). Caustic magnesia with graded particle size is also used as a polishing agent.

Caustic magnesia, magnesium carbonate (precipitated from caustic magnesia), and high-purity magnesia are utilized in preparative chemistry and cosmetics. In the pharmaceutical industry magnesium oxide ($\geq$ 98 % MgO) is used as an antacid, as a powder base, and for magnesium substitution therapy.

A potential use of caustic magnesia is as a slag additive to reduce the dissolution of MgO from refractory bricks in the steel industry. Treatment of the surface of grain-oriented steel transformer sheets decreases magnetic losses. A suspension of caustic magnesia is applied to the sheet and annealed.

4.3.4. Uses of Magnesium Hydroxide

The most important use of magnesium hydroxide is as an intermediate in the production of magnesia. In Japan it is used to replace polyhalogenated diphenyl ether as a flame retardant in thermoplasts processed at 200 – 350 °C. Hydrated alumina cannot be used at these temperatures because of its low decomposition temperature. This application is being tested in Germany [79]. Well-dispersed single $Mg(OH)_2$ crystals seem to be more suitable than agglomerates.

4.4. Economic Aspects

Developments in the production capacities, production, and consumption of magnesia can be briefly summarized as:

1974 – world magnesia shortage [80]
1977 – from shortage to surplus [81]
1981 – agricultural oversupply and industrial underdemand for caustic magnesia [75]
1982 – contraction of refractory magnesia and stagnation of caustic magnesia [82]
1984 – China, the magnesite giant [83]

1987 – the world magnesia industry, smaller but fitter and purer [84]
1989 – magnesia markets – fit for optimism [60]

These changes reflect the dependence of economics on the economic and technological developments in the steel industry. The discovery of highly pure magnesite deposits in Australia in 1985, which will allow magnesia to be obtained directly from the carbonate, has led not only to optimism for producers there, but also to concern among those using the energy-intensive process via magnesium hydroxide.

Recent developments are aimed at reducing energy consumption by improving the filterability of precipitated products, optimizing kiln design, and increasing the size of the periclase crystallites and the bulk density of sintered magnesia. The estimated production capacities for caustic and sintered magnesia are given in Table 6. The estimated production of crude magnesite ore increased from 16×10^6 t/a in 1981 to 20×10^6 t/a in 1988.

4.5. Fused Magnesium Oxide

4.5.1. Properties

Fused magnesia is crystalline magnesium oxide (*mp* 2800 °C) that has been melted in an electric arc. It has the same crystal structure as sodium chloride (i.e., face-centered cubic) and occurs naturally as periclase. No phase changes take place on heating up to the melting point.

Pure fused magnesia is white, although the presence of iron impurities impart a greenish color due to the presence of the mixed crystal compound magnesiowüstite (Mg,Fe)O. When the pale green fused magnesia is heated in air, the color changes to brown owing to the formation of magnesioferrite ($MgFe_2O_4$) [86].

Fused magnesium oxide has a much lower tendency to undergo hydration than sintered magnesium oxide or caustic calcined magnesite [87], and is essentially stable towards the atmosphere. Thus, polished crystal faces of periclase only begin to lose their luster after several weeks, depending on atmospheric moisture content and temperature. Reaction with atmospheric carbon dioxide to form basic carbonates is also noticeable only after several weeks or months.

Fused magnesia is stable in an oxidizing atmosphere up to ca. 2200 °C, above which vaporization and partial dissociation take place. Theoretical vapor pressures of magnesium oxide and partial pressures of its dissociation products in the temperature range 1227 – 2727 °C are given in [88].

In a reducing atmosphere (e.g., in the presence of carbon), fused magnesia is stable only up to ca. 1700 °C. This temperature is also the limit for vacuum use because of the resultant vapor pressure [89].

The most important physical properties of fused magnesia (e.g., thermal conductivity and electrical resistivity) depend on the density, purity, particle size distribution, type, and distribution of the foreign mineralogical phases present. Consequently, data obtained from measurements on single magnesium oxide crystals [90] or pure, polycrystalline magnesium oxide (> 99 %) cannot be regarded as characteristic of commercial fused magnesia.

The following data (see also Chap. 4) are therefore partly based on information from manufacturers of fused magnesia and include the grades most commonly available (MgO content > 92 %, particle size 0 – 400 μm):

Density of pure periclase (theoretical)	3.56 – 3.58 g/cm^3
Knoop hardness	370
Mohs hardness	6
Linear thermal expansion coefficient	
(1000 °C)	14×10^{-6} K^{-1}
Specific heat (c_p)	
100 °C	0.96 kJ kg^{-1} K^{-1}
1800 °C	1.21 kJ kg^{-1} K^{-1}
Thermal conductivity (1000 °C) for densities of	
3.0 – 3.58 g/cm^3	ca. 2.9 – 8.4 W m^{-1} K^{-1}
Dielectric constant, ε (30 Hz – 1 MHz)	11
Electrical resistivity (technical grades, manufacturers' data)	
600 °C	$2\times10^9 - 10^{11}$ Ω · cm
800 °C	$3\times10^8 - 2\times10^9$ Ω · cm
1000 °C	$10^7 - 9\times10^7$ Ω · cm
Electrical resistivity of MgO single crystals (for comparison)	
500 °C	2×10^{13} Ω · cm
1000 °C	6×10^8 Ω · cm

4.5.2. Production

Fused magnesia is mainly produced from naturally occurring magnesite ($MgCO_3$) that

Table 6. Production capacities for sintered and caustic magnesia in 1988/1989 (10^6 t/a) [60]

Country	Sintered magnesia		Caustic magnesia	
	Natural magnesite	Seawater and brines	Natural magnesite	Seawater and brines
EEC	0.6	0.5	0.3	0.1
Western Europe (not EEC) and Asia Minor	0.9	*	0.2	*
Eastern Bloc	2.8	0.14*		< 0.1*
North and South America	0.4	0.7	0.2	> 0.1
Asia	2.0	0.6	0.3	< 0.1
Australia	$\ll 0.1$		$\ll 0.1$	
Africa	$\ll 0.1$		$\ll 0.1$	
World total	6.8	1.9	1.0	0.4

* Including Western Europe (not EEC), Asia Minor and Eastern Bloc.

has been calcined at 1200 – 1400 °C ("dead burned"). The calcined product usually contains > 92 % MgO, 1 – 4 % SiO_2, 0.5 – 2 % CaO, 0.1 – 2 % Al_2O_3, up to 0.2 % Fe_2O_3, and traces of ZrO_2, NiO, Na_2O, K_2O, B_2O_3, and S. Magnesite from seawater (see Section 4.2.2), containing > 97 % MgO, is also used as a raw material.

When fused magnesia is used as an electrical insulator for heating applications (tubular elements), the amount of conductive impurities in the raw material must be minimal. Therefore magnesites that contain, for example, iron oxides or sulfur in appreciable amounts cannot be used. Contamination with sulfur is avoided by calcining the magnesite in wood-fired furnaces.

Fused magnesia is usually produced in a batch process by melting the raw material at 2800 – 3000 °C in electric arc furnaces [91].

The furnaces are heated by either single-phase or, more usually, three-phase a.c. current (Higgins furnace, block-making process). They have a moving base and a conical, water-cooled steel cover. The raw material is added batchwise and acts as a refractory lining for the furnace walls, and the furnace base is usually lined with magnesite bricks or a rammed graphitic material bonded with bitumen. The furnaces are heated by either two or three graphite electrodes. The arcs are struck onto a layer of coke and the electrodes can be vertically adjusted to suit the height of the molten bath.

The current in, for example, a 1000-kW a.c. electric arc furnace (Higgins furnace) is 6000 – 9000 A at 90 – 150 V. The electric power required to produce the fused blocks is ca. 2000 – 4000 kW · h/t [91].

In addition to the traditional block-making process (Higgins furnace), tilting furnace technology is also used for the industrial production of fused magnesia [92]. The melting process is continuous, and the molten product is poured intermittently into water-cooled or refractory-lined molds. Manufacture of fused magnesia by an electric arc trough melting process [93] and in a high-frequency plasma [94] has also been described.

On completion of melting, the electrodes are withdrawn and, after a cooling period, the furnace cover is removed. The fused magnesia blocks can weigh as much as 20 t. After cooling to room temperature, preliminary size reduction is carried out. This is followed by further size reduction of the large broken pieces. The blocks are not homogeneous with respect to structure or chemical composition, and their surface is covered with a coating or crust of agglomerated sintered magnesia.

The impurities in the raw product consist of compounds formed from the quaternary system $MgO-CaO-SiO_2-Fe_2O_3$, e.g., magnesium silicates such as forsterite ($2\,MgO \cdot SiO_2$, *mp* 1890 °C) and monticellite ($CaO \cdot MgO \cdot SiO_2$, *mp* 1500 °C, incongruent melting) whose melting points lie far below that of pure magnesium oxide. The foreign phases are mainly concentrated locally in the surface zone of the fused block and constitute the "melt residues" along with imperfectly melted magnesium oxide (the sintered crust). They are hand separated from the fused product which is a white to pale green

Figure 5. Photomicrograph of polished sections of fused magnesia (dark areas: MgO; light areas: foreign phases monticellite and forsterite)
A) Magnesia produced in a Higgins furnace: foreign phases deposited at the grain boundaries; B) Magnesia produced by casting in a tilting furnace: foreign phases occur mainly as intracrystalline material

crystalline periclase with crystallite sizes from several hundred micrometers up to several centimeters. Hand sorting is the normal industrial method of impurity removal, no better method has yet been found. However, some of the silicate impurities associated with the raw material form inclusions of foreign phases in the crystals of the pulverized magnesium oxide end product. This is because the rate of growth of the magnesium oxide crystals in certain regions of the solidifying melt is greater than the migration rate of the melt residues. Thus, magnesium oxide blocks from a Higgins furnace contain foreign phases (monticellite and forsterite) deposited at the grain boundaries, while magnesium oxide produced by casting from a tilting furnace usually exhibits an intracrystalline distribution of these phases (see Fig. 5). Further treatment of the hand-sorted, size-reduced, fused product includes several size reductions with jaw crushers, roller crushers, and gyratory crushers. Iron particles produced by abrasion and other magnetic impurities are removed by high power magnetic separators. Finally, the finely grained material is classified into particle size ranges using a series of sieves. Fused magnesia intended for electrical heating applications is heated in an oxidizing, neutral, or reducing (although not carbon-forming) atmosphere at 1100 – 1400 °C [95] to remove moisture and carbon (originating from breakdown of the electrodes) and to reduce surface and lattice defects of the magnesium oxide particles.

4.5.3. Uses

Fused magnesia is mainly used as an *insulating material* in the electrical heating industry (→ Insulation, Electric). The particulate material is packed into the space between the heating coil and the outer tube in a heating element for air or liquids [96]. Such elements are used in IR heaters, grill elements, tubular hot plates, and tubular heating elements for ovens, storage heaters, radiators, continuous-flow heaters, washing machines, coffee machines, electric irons, and industrial liquid heating equipment.

The most important factor in this application of fused magnesia is its combination of high electrical resistance with high thermal conductivity. This is superior to that of other refractory oxides or other materials.

The grade of magnesium oxide recommended depends on the application for which the heating element is used (surface temperature of the tube) and the electrical insulation requirements. The grades usually have a size range of 0 – 400 µm and a tap density of 2.2 – 2.7 g/cm^3. The product must have well-defined flow properties, which can be influenced by modifying the particle shape by treatment in a fluidized bed [97].

The electrical and thermal properties of fused magnesia can be improved by adding synthetic or natural minerals (e.g., pyrophyllites [98], fused zircon sand [99], enstatite [100], cordierite [101], or magnesium aluminum silicates [102]) to the prepared mixture of magnesia particles.

The mechanism of action of these additives has not yet been explained.

The chemical composition of some of the industrial grades of fused magnesia (electrical grade) are given in Table 7. The important properties of the mixture of fused magnesia particles (as used for electrical heating, i.e., thermal conductivity, long life time, sinter index, specific electrical impedance, leakage current, tap density, flow rate, grain size distribution) are tested by standard methods (ASTM D 2858, D 2900, D 3026, D 3215, D 3347; DIN 44 872).

Fused magnesia has a further application as a *refractory material*, especially as a lining for induction furnaces and crucibles. Induction furnace linings based on fused magnesia do not shrink (unlike those based on sintered magnesia) owing to the low porosity of the fused material. Magnesia–graphite bricks with an addition of fused magnesia [103] are used in ultrahigh-power furnaces for steel production. The low porosity of the fused magnesia and the size of the periclase crystals considerably improve the corrosion resistance of the refractory lining. The refractory – grade material has a lower SiO_2 content and a higher CaO : SiO_2 ratio than the electrical-grade fused magnesia (i.e., for electrical heating, see Table 7).

In *special applications*, fused magnesia is also used as a molding material for precision casting, as a raw material for magnesium oxide ceramics and as single crystals [104] for optical windows and lenses.

4.5.4. Economic Aspects

The most important countries and companies producing fused magnesia are:

France	Pechiney Electrometallurgie
Germany	Hüls AG
United Kingdom	Universal Abrasives, Thermal Syndicate
Austria	Österreichisch Amerikanische Magnesit AG (refractory grades)
United States	Muscle Shoals Minerals, Tateho America (formerly CE-Minerals), Insultherm
Canada	Baymag (refractory grades)
Japan	Tateho Chemical Ind.

Further information on these manufacturers (e.g., production capacities) is given in [105].

The world consumption of fused magnesia for electrical heating (electrical grade) is estimated to be ca. 35 000 – 40 000 t/a. There are no figures available for refractory grade material because the grades of fused magnesia are not listed separately in the statistics.

5. Magnesium Sulfate

Magnesium sulfate does not occur in nature in anhydrous form. It is found in the form of hydrates and double salts in salt and potash deposits (e.g., in the Unites States, Germany, Russia, and the Ukraine). Magnesium sulfate also occurs in dissolved form in salt lakes.

5.1. Properties

The transformation temperatures of the stable magnesium sulfate hydrates and their solubilities in water are given in Table 8. Table 9 lists the molecular masses, the specific heats, refractive indices, and crystal classes of the anhydrous salt and some of the hydrates [106], [107]. Anhydrous magnesium sulfate can be obtained without decomposition by dehydrating the hydrates at 400 – 500 °C. At 700 °C, however, the compound decomposes to give magnesium oxide, sulfur dioxide, and oxygen. This accounts for the fact that the melting point of magnesium sulfate cannot be accurately determined, it is between 1120 and 1150 °C.

Magnesium sulfate is hygroscopic and absorbs water to form hydrates, finally the heptahydrate. Various hydrates can be obtained by stepwise dehydration of higher hydrates or by crystallization from aqueous solution. Hydrates of analogous composition can be produced by these two methods, but X-ray crystallography shows that their structures differ due to destruction of the crystal lattice during dehydration.

Five stable hydrates can be crystallized from aqueous solutions: $MgSO_4 \cdot 12\,H_2O$, $MgSO_4 \cdot 7\,H_2O$ (Epsom salt, epsomite, Bittersalz), $MgSO_4 \cdot 6\,H_2O$ (hexahydrate), $MgSO_4 \cdot 5/4\,H_2O$ (5/4 hydrate or synthetic kieserite) and $MgSO_4 \cdot H_2O$ (kieserite). Three metastable forms also occur: a second form of the heptahydrate, $MgSO_4 \cdot 5\,H_2O$ (allenite), and $MgSO_4 \cdot 4\,H_2O$ (leonardite). Stepwise dehydration yields hydrates with 1,

Table 7. Chemical composition (typical) of some commercially available fused magnesia grades

Producer	Grade	MgO, wt %	SiO_2, wt %	CaO, wt %	Fe_2O_3, wt %	CaO : SiO_2 ratio	Density, g/cm^3

[d] Apparent density.

5/4, 2, 3, 4, and 6 molecules of water. The solubility of kieserite decreases with increasing temperature due to its negative heat of dissolution. Its dissolution rate increases with increasing temperature and decreasing pH.

Table 8. Stable magnesium sulfate hydrates

Hydrates	Transformation temperature, °C	Solubility, g $MgSO_4$/100 g H_2O
Ice – $MgSO_4 \cdot 12\,H_2O$	−3.9	22.0
$MgSO_4 \cdot 12\,H_2O$ – $MgSO_4 \cdot 7\,H_2O$	1.8	27.2
$MgSO_4 \cdot 7\,H_2O$ – $MgSO_4 \cdot 6\,H_2O$	48.1	49.5
$MgSO_4 \cdot 6\,H_2O$ – $MgSO_4 \cdot H_2O$	67.5	56.6

The acid sulfates $MgSO_4 \cdot H_2SO_4$ and $MgSO_4 \cdot 3\,H_2SO_4$ crystallize when $MgSO_4$ is dissolved in sulfuric acid. Magnesium sulfate ammine hydrates ($MgSO_4 \cdot 3\,NH_3 \cdot 3\,H_2O$, $MgSO_4 \cdot 2\,NH_3 \cdot 4\,H_2O$, and $MgSO_4 \cdot 2\,NH_3 \cdot 2\,H_2O$) are produced when Epsom salt reacts with gaseous ammonia. On reaction with alkali, magnesium hydroxide precipitates. A precipitate of nesquehonite ($MgCO_3 \cdot 3\,H_2O$) is formed with sodium carbonate. After addition of sulfite, phosphate, or stearate solutions, insoluble magnesium sulfite, magnesium phosphate, or magnesium stearate precipitates. Magnesium chloride reacts with magnesium oxide to form oxychlorides; magnesium sulfate reacts in the same way to form oxysulfates ($MgSO_4 \cdot 3\,MgO \cdot 11\,H_2O$ and $MgSO_4 \cdot 5\,MgO \cdot 8\,H_2O$): it can therefore be used as a slower type of sulfate Sorel cement binder (see Sections 3.7, 4.3.3). Magnesium sulfate forms double salts with other salts, most of which also occur in nature:

$KCl \cdot MgSO_4 \cdot 3\,H_2O$ [*67145-93-1*] kainite
$K_2SO_4 \cdot 2\,MgSO_4$ [*13826-56-7*] langbeinite
$K_2SO_4 \cdot MgSO_4 \cdot 4\,H_2O$ [*15226-80-9*] leonite

Table 9. Properties of magnesium sulfate and its hydrates

Compound [CAS No.]	M_r	Specific heat, kJ kg^{-1} K^{-1}	Density, g/cm^3	Crystal class	Refractive index

$K_2SO_4 \cdot MgSO_4 \cdot 2\,CaSO_4 \cdot 2\,H_2O$ [*15278-29-2*] polyhalite

5.2. Occurrence and Raw Materials

The most important source of $MgSO_4$ in Germany is kieserite, which is a constituent of raw potash salt. In the United States, $MgSO_4$ is obtained from langbeinite and in Italy from kainite. The raw salts used by the potash industry in the Ukraine (Stebnik, Kalush) contain magnesium sulfate salts. Magnesium sulfate is also found in the brines of the Great Salt Lake and the Kara – Bogaz Gulf of the Caspian Sea and in other lakes, for example, the Dalagton Basin in China [108]. Seawater bitterns provide a further source (Epsom salt, see Section 5.3.2), the $MgSO_4$ is obtained by cooling. In many countries $MgSO_4$ is also produced from magnesite, dolomite, seawater magnesia, or other magnesium minerals.

5.3. Production

5.3.1. Production of Kieserite ($MgSO_4 \cdot H_2O$)

Production of Kieserite by Selective Dissolution of Residues from Potash Salt Production. The raw material for this process is a crude salt that contains kieserite (hard salt, carnallitite). The sodium chloride is selectively dissolved from residues of potash salt production. The filtered or centrifuged residues obtained during the production of potassium chloride are first washed with a partially saturated NaCl solution from a subsequent washing step. The NaCl in the residues is readily soluble and dissolves in the NaCl solution until it becomes saturated; the kieserite, however, remains largely undissolved due to its slow dissolution rate. Kieserite and residual NaCl are separated from the washing medium with a bucket conveyor or elevator. The kieserite – NaCl mixture is then washed with water in a second stage to dissolve any residual NaCl. Washing is performed in pipes lined with fused basalt that are several hundred meters long. The quantity of NaCl solution produced can be minimized by using the electrostatic production process (see below).

Ecological Aspects. The saturated NaCl solution contains 280 – 300 g NaCl per liter. Its disposal entails considerable ecological problems. Large quantities have been stored in jointed rock formations (platy dolomite) that are filled with slightly salted groundwater, but with only limited capacity [109].

Production of Kieserite by Flotation. Kieserite can be separated from rock salt by flotation. Prestaminol, oleic acid, fatty alcohol sulfates, or oxystearic acid are used as flotation agents for kieserite and anhydrite ($CaSO_4$) [110]. The kieserite can be further purified by separating it from the anhydrite and/or langbeinite. This is achieved by using oleic acid or a fatty acid amine as a flotation agent for the kieserite [111–113].

Electrostatic Separation of Kieserite. The electrostatic separation process (ESTA process) developed by Kali und Salz AG (Germany) [114] eliminates the formation of the large quantities of NaCl solution produced in the selective dissolution process (see above) [115], [116].

Kieserite can be electrostatically separated in one or two stages. In the one-stage process the raw salt is treated with aliphatic or a mixture of aliphatic and aromatic monocarboxylic acids that are combined with ammonium salts of aliphatic carboxylic acids, usually ammonium acetate. The salt is then heated at a defined relative humidity and electrostatically charged [117]. The kieserite becomes positively charged with respect to the potassium chloride and sodium chloride. Repeated separation of the kieserite deposited at the negative electrode yields $MgSO_4$ in a pure, marketable form.

In the two-stage process rock salt is first separated and then the highly pure kieserite. The raw salt is first treated with aromatic monocarboxylic acids, heated at a defined relative humidity, and then charged [118]. The rock salt becomes positively charged with respect to the

potassium chloride and the kieserite. The rock salt is removed and the KCl – kieserite mixture separated at the positive electrode. The mixture is treated with aliphatic monocarboxylic acids, heated once again at a defined relative humidity, and charged [117]. The kieserite now becomes positive with respect to the potassium chloride. Repeated separation of the kieserite deposited at the negative electrode gives a pure, marketable product.

The potassium chloride fraction is still contaminated with kieserite and sodium chloride; it is used for the production of potassium salts [119], [120].

Production of Granulated Kieserite. After addition of 3 parts of a solution containing preferably 18 wt % Na_2SO_4 or 20 wt % Na_3PO_4 to 47 parts of kieserite, the product can be pressed in a moist state and then ground [121]. After addition of ammonium sulfate and hot magnesium sulfate solution, kieserite can also be granulated with a dish granulator [122]. Mono-, di-, or polysaccharides (usually lactose) are highly suitable additives for preparing these rolled granulates. The kieserite should have a broad particle size range; at least 20 % of the particles must be less than 0.09 mm in diameter [123]. Addition of phosphate allows production of a rolled granulate of high strength even without drying [125], [126].

5.3.2. Production of Epsom Salt

Production of Epsom Salt from Kieserite. Kieserite is dissolved in hot water (90 °C) to give a clear solution. Dissolution is performed in single large vats with capacities of up to 500 m^3 that have a sieve base covered with coconut mats. The process has the disadvantage that the throughput is very low and the sieve plate gradually becomes encrusted with anhydrite and double salts. Kali und Salz AG therefore uses a multichamber cascade with slow stirring; the slurry density in the chambers is 70 wt %. Hot water is added from below and kieserite from above. The solution produced at the top of the cascade contains 400 g/L $MgSO_4$. At the bottom the residue containing anhydrite can be removed at intervals [127].

The hot concentrated solution is cooled in multistage vacuum coolers in which large crystals of Epsom salt are formed. After thickening, the Epsom salt is either filtered or centrifuged. The moist salt is dried in drum driers with air at ca. 50 °C.

Production of Epsom Salt from Magnesia, Magnesite, and Other Materials. Magnesium sulfate solution can be produced by treating seawater magnesia (MgO) or magnesite ($MgCO_3$) with sulfuric acid. Waste sulfuric acid contaminated with organic compounds may be used [128]. The resulting solution is clarified, evaporated to a density of 1.35 – 1.36 kg/L, and processed as described above. The product can be spray dried at 150 °C. Dolomite, olivine, serpentine, or peridotite can also be reacted with sulfuric acid. Magnesium sulfate can also be obtained by adding MgO to pyrite during roasting and subsequent extraction [129].

Waste serpentine from asbestos production can be reacted with ammonium sulfate above 250 °C and the reaction mixture extracted with water [130], [131]. The resulting solution is evaporated and the Epsom salt crystallizes.

Production of Epsom Salt from Boron- and Magnesium-Containing Raw Materials. The borate raw material containing SiO_2, Fe oxide, and Mg is decomposed with H_2SO_4. The solution is separated from the slurry. After crystallization, H_3BO_3 and $MgSO_4$ are separated by flotation [132].

Production of Epsom Salt from Seawater Bitterns or Salt Lake Brines. Pure Epsom salt can be obtained directly from seawater bitterns and from brines from salt lakes with a high $MgSO_4$ content (e.g., Kara – Bogaz Bay) by diluting with water and cooling to – 10 °C [133], [134].

Production of Epsom Salt from Langbeinite. Langbeinite ($K_2SO_4 \cdot 2\,MgSO_4$) is decomposed by treating with water for 6 h at 50 – 60 °C to produce $MgSO_4 \cdot 6\,H_2O$. On cooling the mother liquor to 20 – 35 °C the Epsom salt crystallizes [135].

Production of Epsom Salt from Magnesite or Dolomite and Gypsum. A mixture of ground dolomite and gypsum is treated with steam at

1.5 – 3.0 MPa and filtered to remove the $CaCO_3$ from the $MgSO_4$ solution [136]. Magnesite is calcined at 760 – 835 °C, hydrated in the presence of gypsum at 56 – 60 °C, and carbonized with carbon dioxide. The $MgSO_4$ solution is filtered to remove the $CaCO_3$ [137] and processed to obtain Epsom salt.

5.3.3. Production of Anhydrous Magnesium Sulfate

Anhydrous $MgSO_4$ does not occur in nature and can only be produced by dehydrating $MgSO_4$ hydrates. Kieserite is purified by removing anhydrite and langbeinite in a special electrostatic procedure. It is subsequently washed with water to remove residual chloride [138]; langbeinite and anhydrite may also be removed by flotation (Section 5.3.1). It is then dehydrated by heating at ca. 500 °C in a gas-heated calcination drum and finally cooled [139]. If Epsom salt is used as starting material instead of kieserite, six molecules of water of crystallization can be removed at < 70 °C and the remaining molecule at 500 °C [140].

5.4. Quality Specifications and Analysis

Magnesium sulfate is sold as kieserite (73 – 83 wt % $MgSO_4$), 99.9 % pure Epsom salt (48.8 % $MgSO_4$), and anhydrous $MgSO_4$ (> 98 % $MgSO_4$). Epsom salt is marketed as a chemically pure product, as a clinical product that complies with pharmacopeia specifications, and as an analytical grade reagent. Maximum contamination limits for clinical grades vary according to the pharmacopeia: chloride 100 – 300 mg/kg, iron 20 mg/kg, and heavy metals 10 mg/kg. Maximum limits for arsenic, selenium, and other substances may also be specified.

The analytical procedures used for quality control are the same as those employed for magnesium chloride (see Section 3.5). Sulfate, however, is determined by a gravimetric method [141].

5.5. Transportation and Storage

Depending on the atmospheric humidity, Epsom salt can lose or absorb water during storage and thus tends to harden. It is therefore preferably supplied in Clupack valve sacks. Kieserite is transported in railroad cars and trucks, both in bulk and in valve paper sacks. Anhydrous $MgSO_4$ is also supplied in bulk and in sacks.

5.6. Uses

Large quantities of kieserite and Epsom salt are used in Germany for the production of potassium sulfate (→ Potassium Compounds). Kieserite is used in fertilizers, either as an additive in multinutrient fertilizers or directly to combat magnesium deficiency. In multinutrient fertilizers kieserite aids granulation and improves granulate properties. In cases of acute magnesium deficiency, Epsom salt is an especially effective foliar fertilizer.

Magnesium sulfate is a component of magnesium binders (Sorel cement, see Section 3.7) and can also be used as a binding agent in the production of magnesia bricks. Addition of $MgSO_4$ and $Al_2(SO_4)_3$ leads to the formation of spinels during firing of refractory products. It is also used to produce abrasive wheels. Decomposition of $MgSO_4$ in refractory products at > 1100 °C results in the formation of sulfur dioxide and thus gives a light product. Magnesium sulfate is also used in the production of Portland cement from blast furnace slag and as an additive in gypsum-containing building materials.

Magnesium sulfate is employed in the sugar industry for refining the sugar liquor and for improving the sugar yield from molasses (Quentin procedure) [142]. It is utilized in fermentations for the production of amino acids, antibiotics, bakers' yeast, biomass, and citric acid. It increases the activity of glucose isomerase, the enzyme which converts glucose to fructose.

In the aluminum industry, a mixture of kieserite and calcium oxide or hydroxide is used to precipitate contaminants from aluminate solutions. Magnesium sulfate is also employed in fixative baths used to color aluminum surfaces by means of anodic oxidation. It is a component of the electrolytic baths used for chrome plating, zinc plating, copper plating, nickel plating, and

the electroplating of tungsten, manganese, vanadium, cobalt, and cobalt alloys. It is also used in the phosphating of iron.

In the glass industry, sinters with a defined porosity can be obtained by incorporating $MgSO_4$ of a defined particle size and then leaching it. Magnesium sulfate is used as an additive in enamels and pigments. In the detergent industry it prevents gel formation during spray drying; magnesium silicate synthesized from $MgSO_4$ stabilizes peroxides and thus improves bleaching. Magnesium sulfate is also used as a make-up chemical in the sulfite pulping process and as a stabilizer for cellulose during oxygen bleaching of pulp. In the paper industry it is used in the preparation of paper for coating and in the deinking of recycled printed paper.

Other uses include treatment of waste and wastewater and soil stabilization. The compound is also used as an additive in drilling fluids, lead – acid batteries, oil and coal fuels, ore preparation, "isotonic" beverages, low-NaCl salt mixtures, cosmetics, bath salts, infusions, photographic developers, dye baths, and animal feeds.

In the plastics industry $MgSO_4$ is employed as a coagulant, polymerization catalyst, stabilizer, and flame retardant. In the petrochemical industry it is employed together with manganese chloride for cracking petroleum. Use of $MgSO_4$ in the leather industry makes the leather more supple, increases its weight, and removes calcium carbonate. Magnesium sulfate is also used as a heat storage medium and as a raw material for the production of magnesium aluminate, magnesium alumosilicate, and other magnesium compounds. One of the important applications of Epsom salt is as a laxative.

5.7. Economic Aspects

Epsom salt is produced in many countries, the most important being Germany, Japan, and the United States. It is usually consumed in the country in which it is produced. Only Germany, and the Peoples Republic of China export the compound. Other commercially available products are kieserite, anhydrous $MgSO_4$, and fertilizers containing kieserite (Germany) and langbeinite (USA). Estimated production figures are given in Table 10.

5.8. Toxicology and Occupational Health

Magnesium sulfate and its hydrates are not dangerous to human health when handled in accordance with the appropriate regulations. The LDL_0' (mouse, oral) for $MgSO_4$ is 5000 mg/kg. Magnesium sulfate is not listed in the EEC directive of May 5th, 1976 concerning the discharge of harzardous substances into water; it is classified as a nonhazardous substance in the EEC directive of June 12th, 1987 (WGK:O).

6. Organomagnesium Compounds

Organomagnesium compounds have been of outstanding importance in preparative organic chemistry ever since Victor Grignard (1900) discovered that they are readily prepared from organic halides and elemental magnesium in ethers [143]. In 1912 Grignard received the Nobel Prize for their discovery and for the development of their synthetic potential. As a divalent element, magnesium can bond with one (RMgX, X is usually a halogen, Grignard reagent), or two organic groups (R_2Mg); this bonding does not, however, satisfy the coordination requirements of magnesium (Section 6.1).

The production, structure, and properties of organomagnesium compounds have been summarized in several reviews [144–149]. Industrial use is generally limited to the production of fine chemicals, in which the upper limit is of the order of several tons.

Occasionally, they are used for the synthesis of (polymerization) catalysts [150], [151]. Their use for the production of organic lead derivatives (e.g., tetramethyl lead) is declining.

6.1. Properties

Compounds of the type RMgX or R_2Mg (R = aryl or alkyl) are generally colorless solids unless R is a resonance-stabilized, colored anion. With few exceptions (e.g., *sec*-dibutylmagnesium, dineopentylmagnesium, dicyclopentadienylmagnesium) they are nonvolatile; only the dialkyl compounds where

Table 10. Estimated production and consumption of magnesium sulfate products in 1988 (10^3 t)

Product	Production	Consumption in fertilizers	Consumption in other areas
Anhydrous $MgSO_4$	110	40	70
Kieserite ($MgSO_4 \cdot H_2O$)	2 300	2 250	50
Epsom salt ($MgSO_4 \cdot 7\,H_2O$)	280	180	100
Sulfate of potash magnesia	1 000	1 000	
Total	3 690	3 470	220

$R > C_4H_9$ are soluble in hydrocarbons, especially aromatic hydrocarbons. Solubility, however, increases considerably in the presence of one or two equivalents of a coordinating ether, especially if intramolecular coordination occurs (i.e., by an ether function incorporated in the substituent R).

The structures of organomagnesium compounds in the solid state are being increasingly documented by crystal structure analysis. In the great majority of compounds, magnesium has a coordination number of four, which is generally attained by coordination with two Lewis bases, usually ethers (e.g., $RMgX \cdot 2\,Et_2O$); in the absence of a base, association takes place. The coordination sphere around the tetracoordinated magnesium is a distorted tetrahedron [145]. Association takes place by means of three-center, two-electron bonds, leading to the formation of dimeric or polymeric structures [152], [153]:

Organomagnesium compounds are thermally stable up to 100 – 170 °C, but at higher temperatures they can decompose explosively. They are extremely sensitive in air (i.e., in the presence of oxygen) and particularly toward water; they can sometimes ignite spontaneously. In ethereal solution the relatively heavy ether vapor protects them to some extent from exposure to air and thereby against decomposition. For small amounts or very pure preparations, an inert atmosphere of nitrogen or, preferably, argon, is recommended; in extreme cases an evacuated system should be employed.

For preparative purposes organomagnesium compounds are not isolated as such, but are used directly in solution following their preparation. Their structure in solution is basically the same as that in the crystal; nevertheless, a fundamental difference is that an equilibrium can exist between the various possible species, the position of which depends on the organic group R, the halogen X, the solvent Y, the concentration, and the temperature:

The most important of these equilibria is that between RMgX and R_2Mg, the so-called Schlenk equilibrium. It is strongly dependent on the solvent and lies, for example in diethyl ether, well to the left-hand side, whereas in tetrahydrofuran an almost statistical distribution exists (i.e., $R_2Mg : MgX_2 : 2\,RMgX = 1 : 1 : 2$).

Organomagnesium solutions can be quantitatively analyzed by various methods [154]. In addition to qualitative color tests [155], titrations can be used in which the active carbon–magnesium bond is either titrated directly with *sec*-butanol in the presence of a color indicator [156] or indirectly with hydrochloric acid after hydrolysis to give the free base, if necessary together with complexometric titration of the magnesium. Less convenient, but nevertheless reliable, is the formation and quantitative

determination of derivatives, e.g., with carbon dioxide or chlorotrimethylstannane.

$$RCOOH \xleftarrow{CO_2, H^+} RMgX \xrightarrow{ClSn(CH_3)_3} RSn(CH_3)_3$$

Apart from their instability in air and their caustic basic properties, organomagnesium compounds and the precipitated inorganic magnesium salts produced during their use display no pronounced toxicity or side effects of environmental concern. The pyrophoric properties of the compounds and the high flammability of the ethereal solvents demand the usual protective measures.

6.2. Production

In practice the synthesis of Grignard reagents RMgX (X = halide) from organic halides RX and metallic magnesium is by far the most important preparative method. The Grignard reagents are used directly or indirectly as starting materials for the production of other (organometallic) compounds and also for the diorganylmagnesium compounds R_2Mg.

6.2.1. Grignard Reagents

The production of solutions of Grignard reagents (RMgX) according to the equation

$$R-X + Mg \xrightarrow{2\,Y} R-Mg-X \cdot 2\,Y$$

R = alkyl or aryl group
X = halogen
Y = solvent (usually diethyl ether or tetrahydrofuran)

presents few problems if suitable protective measures are observed [145], [157]. The fluorides react very sluggishly; the iodides are very reactive and side reactions, particularly Wurtz coupling, occur frequently. Side reactions also occur to a small extent with the chlorides and the bromides:

$$2\,R-X + Mg \longrightarrow R-R + MgX_2$$

Organic bromides are most suitable for the production of Grignard reagents, but are frequently replaced in industrial applications by the cheaper chlorides.

The initiation of the reaction leading to formation of the Grignard reagent presents a considerable problem; it can be delayed or even fail as a result of reagent impurity or the low reactivity of the organic halide. Various strategies have been developed to overcome these difficulties [157], of which only a few will be mentioned here. Impurities causing delay in initiation can often be eliminated by the addition of a small amount of RMgX, possibly from an earlier batch. Most methods depend, however, on the activation of the magnesium, which is normally used in the form of turnings. Mechanical activation can be achieved by vigorous stirring or with ultrasound [158], chemical activation with numerous reagents (e.g., iodine, bromoethane, 1,2-dibromoethane, mercuric chloride, amalgam). A highly reactive, finely divided magnesium suspension can be obtained by (co-)sublimation of the metal (with the substrate), by reduction of magnesium chloride with potassium [159], or by heating anthracene – magnesium in tetrahydrofuran [160].

For reasons of cost and safety (inflammability, peroxide formation), the use of hydrocarbon solvents instead of the usual ethers is of interest. The synthesis of Grignard reagents in hydrocarbons (e.g., methylcyclohexane [150]) or an excess of the organic halide [161] unfortunately requires more severe conditions and leads to halogen-deficient products, whose reactivity often differs from that of the Grignard reagents synthesized in an ether solvent. Furthermore, solubility is also poor, so that suspensions must be used; however, the higher aliphatic halides (especially the iodides) give soluble organomagnesium compounds [162].

A relatively recent development is the synthesis of di-Grignard reagents, particularly those with only a few (1 – 3) carbon atoms between the two functional groups [163], [164]; they are of interest mainly in organometallic chemistry. Examples are the 1,1- or 1,3-di-Grignard reagents:

$$Br(CH_2)_nBr + Mg \xrightarrow[Mg]{n = 1, 3} BrMg(CH_2)_nMgBr$$
$$\downarrow n = 2$$
$$MgBr_2 + CH_2{=}CH_2$$

Even a tri-Grignard reagent has been produced (in 44 % yield) [165]:

Finally, mention should be made of the Barbier reaction, i.e., the reaction of an organic halide with magnesium in the presence of the substrate (e.g., a ketone that is to be alkylated). This reaction was discovered by GRIGNARD's professor BARBIER and is the predecessor of the Grignard reaction. The Barbier reaction gives better yields when the Grignard reagents can only be isolated in poor yields, for example, with many allyl, benzyl-, or polyhalides [157], [158], [166], [167]: The method has been adapted for performance on a semi-industrial scale [168].

Other preparative methods have limited application and are only of special interest, e.g., the metallation of acidic hydrocarbons, metathesis with organolithium or organosodium compounds, metal exchange reaction with organomercury compounds, addition to unsaturated systems, or comproportionation of MgR_2 and $MgBr_2$ by the Schlenk equilibrium (in diethyl ether):

$$RMgX + R'C{\equiv}CH \longrightarrow R'C{\equiv}CMgX + RH$$

$$2\ \text{C}_5\text{H}_5 + Mg \longrightarrow (C_5H_5)_2Mg + H_2$$

$$RLi + MgBr_2 \longrightarrow RMgBr + LiBr$$

$$RHgBr + Mg \longrightarrow RMgBr + Hg$$

$$(CH_3)_3CMgCl + CH_2{=}CH_2 \longrightarrow (CH_3)_3CCH_2CH_2MgCl$$

$$2\ CH_2{=}CH_2 + MgH_2 \xrightarrow[\text{THF}]{\text{Cat.}} Mg(CH_2CH_3)_2$$

$$MgR_2 + MgBr_2 \longrightarrow 2\ RMgBr$$

6.2.2. Diorganylmagnesium Compounds

Dialkyl- and diarylmagnesium compounds (R_2Mg) are generally of only limited practical importance. They are most frequently obtained from Grignard reagents by displacing the Schlenk equilibrium (see Section 6.1). In hydrocarbon solvents, the equilibrium already lies to the right. In diethyl ether, the equilibrium can be shifted by the addition of dioxane and precipitation of poorly soluble magnesium bromide–dioxanate [144], [145].

$$2\ RMgBr \underset{\times}{\overset{\text{Hydrocarbons}}{\rightleftharpoons}} R_2Mg + MgBr_2 \downarrow$$

$$2\ RMgBr \underset{\times}{\overset{\text{Dioxane}}{\rightleftharpoons}} R_2Mg + MgBr_2 \cdot (C_4H_8O_2)_2 \downarrow$$

Very pure R_2Mg can be obtained by shaking diorganylmercury compounds for several days at room temperature in ether with an excess of magnesium.

6.3. Uses

Organomagnesium compounds, especially Grignard reagents, have a wide range of application on account of their easy accessibility and their high reactivity. In organic synthesis they serve as nucleophiles for formation of carbon–carbon bonds. In organometallic chemistry they are used for the nucleophilic alkylation or arylation of metal salts; this reaction is suitable for the majority of main group and transition metals with a greater electronegativity than magnesium. In both areas the more reactive organolithium compounds are competing with the Grignard reagents. However, since the reactivity of Grignard reagents is usually high enough, they have lost little in popularity. This is also due to their ease of manipulation and their lower price, especially in industrial quantities.

The broad spectrum of reactions of Grignard reagents toward C=O, C=N, C≡N, C−X, C−H, and M−X groups can be illustrated by the following examples [144], [145], [147].

$$
\begin{aligned}
RMgX + R'CH{=}O &\rightarrow RR'CHOH \\
+ R'_2C{=}O &\rightarrow RR'_2CHOH \\
+ R'COOCH_2CH_3 &\rightarrow R_2R'COH \\
+ CO_2 &\rightarrow RCOOH \\
+ R'_2C{=}NR'' &\rightarrow RR'_2C{-}NHR'' \\
+ R'C{\equiv}N &\xrightarrow{\text{Cat.}} RR'C{=}O \\
+ R'X &\rightarrow R{-}R' \\
+ R'H &\rightarrow R{-}H + R'MgX \\
+ MCl_n &\rightarrow MR_n
\end{aligned}
$$

(M = metal from group 3–15)

L = substituent or ligand ($n \geq 3$)

Magnetic Information Storage → Information Storage Materials

Magnetic Materials

Wilhelm Ervens, Krupp Widia, Essen, Federal Republic of Germany

Heinrich Wilmesmeier, Krupp Widia, Essen, Federal Republic of Germany

1. Introduction

Magnetism is a fundamental property of matter. All substances exhibit some form of magnetic behavior, which has its ultimate source in the magnetism of atomic nuclei and electrons.

The magnetism of materials varies in nature and strength depending on their composition and state of order. The principal state of order in industrial magnetic materials is that of ferromagnetism, which (along with some variations) is discussed in Section 2.3.

Industrial magnetic materials are classified as soft or hard in accordance with how they behave in the presence of external fields. Hard magnetic materials are also called permanent magnets.

Soft magnetic materials find use where the magnetic effects associated with either permanent magnets or electromagnetic fields must be concentrated or shielded, or where low-loss transformation, exact transmission, modulation, or regulation of electrical signals is needed.

The practical importance of hard magnetic materials stems from their ability, once magnetized, to act on other ferromagnetic materials without contact, attracting or, in the case of other permanent magnets, repelling them. With no energy input and therefore at no operating cost, permanent magnets provide a magnetic flux or a magnetic field.

Magnetic materials are found in nearly every area of daily life. They perform coupling, modulating, or regulating functions in equipment and devices based on electromagnetic principles (e.g., motors, generators, loudspeakers, transformers) and also in magnetomechanical systems (e.g., clutches, separators). Magnetic materials are indispensable in office equipment, computer hardware, automobiles, entertainment electronics, communications, household appliances, and medical instruments.

With the rapid development of high-performance semiconductor components and integrated electronic circuits, the magnetic components and inductive devices used in electrical equipment must also satisfy more and more stringent requirements, chiefly that of smaller size with equal or enhanced efficiency. As a consequence, hard magnetic materials must have higher energy contents (see Section 3.2), while soft magnetic materials require improved magnetic conductances (see Section 3.3). Complicated shapes and close tolerances must also be realized, and stringent standards of thermal stability and corrosion resistance have to be satisfied.

Recently, major advances have been made in both hard and soft magnetic materials, due to newly developed materials and further development of existing ones. Important hard magnetic materials include primarily alloys containing rare earth metals; these are described in Section 4.2. Rapidly quenched amorphous and nanocrystalline materials and new plastic-bonded powder composites represent significant innovations in soft magnetic materials (see Section 5.2).

Thus, together with the classical hard and soft magnetic materials, a wide range of magnetic materials is available for various applications whose importance, both technical and economic, is steadily increasing.

2. Forms of Magnetism in Matter

The magnetic phenomena exhibited by matter depend on the electronic configuration of the atom, the crystalline and molecular structure, and the resultant coupling between electrons.

Magnetism is an inherent property of materials, arising from the orbital and spin magnetic moments of the nucleus and the electrons. The dominant contribution to macroscopic magnetic behavior is due to the electrons.

2.1. Diamagnetism

Diamagnetism, a form of magnetism originating directly from the magnetic moments of the atom's constituents, is not associated with any particular state of aggregation. All substances are diamagnetic.

Diamagnetic materials are displaced out of inhomogeneous magnetic fields. Usually, however, diamagnetism is masked by other, stronger forms of magnetic interaction (see Sections 2.2 and 2.3).

Because of mutual cancellation of the individual moments, diamagnetic substances do not exhibit a resultant external magnetic moment. In the presence of an external magnetic field H, the diamagnetic moment or polarization J results from an additional precessional motion (Larmor precession) about the direction of the external field. The polarization J points in the opposite direction to H. These two quantities are linked by the negative susceptibility χ:

$$J = \mu_0 \chi H \tag{1}$$

where μ_0 is the magnetic field constant, equal to $4\pi \times 10^{-7}$ Vs/Am. Examples of diamagnetic substances are the noble gases, metals such as silver, gold and copper, water, and organic compounds such as ethanol and benzene.

2.2. Paramagnetism

If the magnetic moments of an atom do not completely cancel because of the electronic configuration, the atom exhibits a resultant moment. This is the case in paramagnetic substances.

In an external magnetic field, these moments, which were initially in a disordered state, align parallel to the field; this process competes with thermal disordering of the moments. The paramagnetic susceptibility χ is positive and depends strongly on temperature. At room temperature, it is of the order of $10^{-3} - 10^{-6}$.

Examples of paramagnetic substances are aluminum, potassium, magnesium, sodium, many gases, salts of the iron-group metals, and also all ferromagnetic and ferrimagnetic substances above the Curie temperature.

2.3. Ferromagnetism

Ferromagnetism is confined to the solid state of matter. In addition to the uncompensated magnetic moments of the individual atoms, in ferromagnetic materials there is also an exchange interaction between neighboring atoms that leads to adjacent moments becoming parallel in competition with the disordering effect of thermal motion. This is regarded as a spontaneous polarization that is inherent to the material and is present in macroscopic domains (Weiss domains) of the ferromagnetic material – even in the absence of an external magnetic field – and has its maximum value at absolute zero (see Fig. 1 A). If thermal energy is supplied, the order decreases (Fig. 1 B) until the paramagnetic state comes into being (Fig. 1 C) at the Curie temperature T_C, which is characteristic of the material. Ferromagnetism is thus a collective phenomenon based on an energetic interplay of many atoms in a definite geometrical association.

Despite its spontaneous magnetization in macroscopic domains, a ferromagnetic material can exhibit zero external net magnetism. The reason is that the entire volume of the material does not consist of a single domain spontaneously magnetized in one direction, but is subdivided into many domains in such a way as to minimize the magnetostatic energy (see Fig. 1 D). All these domains are spontaneously magnetized, but in various directions, so that the resultant moment can theoretically take any value between zero and the saturation polarization J_s(T), depending on the prehistory.

Changes in magnetization in the presence of an external magnetic field take place in one of two ways: favorably oriented domains grow by displacement of the domain walls (Bloch wall movement, Fig. 1 E), or entire domains collectively rotate their magnetic moments. Figure 1 F shows the ferromagnetic domain structure in FeCu.

The complexity of these processes means that the ferromagnetic susceptibility is not only markedly temperature dependent but also dependent on field strength, so that no single-valued relationship between the polarization J and the field strength H exists:

$$J = \mu_0 \chi(H) \cdot H \tag{2}$$

The relationship is illustrated by the hysteresis loop described in Section 3 (see Fig. 2).

Figure 2. $J(H)$ and $B(H)$ hysteresis curves of ferromagnetic materials, showing the virgin curve (a) measured on magnetization of a previously demagnetized sample and the demagnetization curve (b)

The ferromagnetic susceptibility can have values between 0 and 10^6, depending on the material. Typical ferromagnetic materials are the elements Fe, Ni, and Co, as well as some of their alloys. Amorphous alloys can also exhibit ferromagnetic behavior.

2.4. Ferrimagnetism and Antiferromagnetism

Ferrimagnetic materials exhibit a structure consisting of two interpenetrating lattices (spinel structure), whose magnetic moments are unequal and opposite in direction. The effective moment is thus a differential moment, so that only small polarization values are obtained. This behavior, the much lower electrical conductivity, and the mechanical properties are the essential differences between ferrimagnetic and ferromagnetic materials.

The case in which the magnetic moments of the two sublattices cancel each other, so that the spontaneous magnetization with no external field is zero, is termed antiferromagnetism.

3. Magnetic Quantities and Their Measurement

3.1. General

Important terms that describe the magnetic properties of matter are the magnetic flux density or induction B, the magnetic polarization J, the magnetic field strength H, and other quantities associated with specific material behavior, such as the relative permeability μ or the magnetic susceptibility χ ($\mu = 1+\chi$).

The magnetic field and flux are related to electric field quantities by the fundamental vector equations of electric field theory, the most important of which are Maxwell's first and second laws:

$$\mathrm{curl}\ \vec{H} = \vec{j} \tag{3}$$

$$\mathrm{curl}\ \vec{E} = \partial \vec{B} / \partial t \tag{4}$$

The first equation relates the magnetic field strength H to a steady current distribution with current density $\vec{j}$. The law states that any conductor through which a current flows is surrounded by closed lines of magnetic field. For the magnetic field inside a long cylindrical or toroidal coil having length l and n turns, and carrying a current I, the magnetic field derived from (3) is $H = n\,I/l$. Accordingly, magnetic field strength has dimensions of current over length and units of A/m.

The second equation formulates the law of induction, according to which the time variation of a magnetic flux Φ through a surface A ($\Phi = BA$) induces an electrical voltage U. The unit of magnetic flux density is Vs/m^2 (1 Vs/m^2 = 1 Tesla).

The physical relationships expressed by the two formulas, modified in a variety of ways, explain how magnetic quantities can be measured by determining electrical quantities.

Other methods for measuring magnetic quantities are based on the force exerted by magnetic fields on electrically charged particles, such as the charge carriers in semiconductors. Probes employing this principle are called magnetoresistance cells or Hall probes. Another technique used for the precise determination of magnetic field strengths is nuclear resonance.

In order to identify and evaluate magnetic materials, the dependences of induction B and polarization J on magnetic field strength H must be known. Plots of these relationships for both soft magnetic and hard magnetic materials give hysteresis curves, though the crucial parameters characterizing the material are different in the two cases. Figure 2 shows a complete hysteresis loop in $J-H$ and $B-H$ plots, along with the associated "virgin" or initial magnetization curve obtained on the first magnetization of a magnetic material. The quantities B and J are related as follows:

$$B = \mu_0 H + J \tag{5}$$

The induction B thus consists of the polarization of the material J plus the polarization of a vacuum $\mu_0 H$.

The area enclosed by the hysteresis loop represents the work transformed to heat in a complete magnetization and demagnetization cycle. The quantities indicated in Figure 2 are explained in Sections 3.2 and 3.3.

3.2. Parameters of Hard Magnetic Materials

The quantities that describe a permanent magnet are the remanent induction, or remanence B_r measured in Tesla (T), the coercive forces of polarization H_cJ and induction H_cB in kA/m, and the energy product $(BH)_\mathrm{max}$ in kJ/m^3. These

quantities are labeled in the hysteresis curve of Figure 2. The branch of the loop in the second quadrant is called the demagnetization curve. The demagnetization curve is generally sufficient to characterize a hard magnetic material. It shows how the polarization (J – H plot) or the induction (B – H plot) behaves in the presence of an opposing magnetic field.

The coercive force H_{cJ} or H_{cB} is the external field strength at which J or B becomes zero. This is a measure of the stability of the magnetic state; H_{cJ} is always greater than or equal to H_{cB}.

The remanence B_r or the polarization J_r ($B_r = J_r$) is the induction in a field $H = 0$. Since a magnet is always subject to its own field, this quantity can be determined only in a closed magnetic circuit.

The energy product $(BH)_{max}$, the largest possible product of the B and H values along the demagnetization curve, is a measure of the magnetic quality of a permanent magnet. The greater this maximum for a material, the smaller the volume of magnet is needed to produce a given flux in the air gap of a magnetic system (the working region of the magnet). This fact accounts for the importance of high-quality permanent magnets for miniaturized components in many fields of modern technology.

At a remanence B_r, the theoretical $(BH)_{max}$ is given by

$$(BH)_{max} = \frac{B_r^2}{4\mu_0} \tag{6}$$

This value is reached when the coercive force H_{cB} is at least

$$H_{cB} = \frac{B_r}{2\mu_0} \tag{7}$$

Whether and to what extent this is really the case depends on the mechanism responsible for generating the coercive force. A marked magnetic anisotropy along one crystal axis, as is observed in hard ferrites and rare earth (RE) magnetic materials, is a prerequisite for a strong coercive force.

Thus, whereas hard ferrites and RE – Co and RE – Fe magnetic materials attain energy products within a few percent of $(BH)_{max}$ as calculated by Equation 6, in the AlNiCo and Cr – Fe – Co materials, in which precipitates having form anisotropy give rise to the coercive force, the $(BH)_{max}$ actually attained is usually less than 20 % of the theoretical maximum value.

Various measuring systems are available for determining the parameters of permanent magnets. Examples are highly sensitive fluxmeters, with which the integrated flux of the permanent magnet can be determined by the use of a search coil, and magnetic-field probes that use the Hall effect or a change in resistance to detect magnetic influences [2].

The measurement of the demagnetization curve or of the entire hysteresis loop is carried out in closed magnetic circuits consisting of a measuring yoke in which the magnetic specimens is clamped. The specimen, magnetized externally or in the yoke, is demagnetized by applying an opposing field. The flux variation of the magnet is determined by means of a search coil; the instantaneous induction B or polarization J of the magnet as a function of the opposing field strength is determined by measurement with a search coil or a Hall probe [3], [4].

3.3. Parameters of Soft Magnetic Materials

In contrast to the materials used for permanent magnets, magnetically soft materials must be easily magnetized or remagnetized. Even weak driving fields (a typical value for material characterization is $H = 0.4$ A/m) must produce the greatest possible flux density in the material.

The relation between B and H is described in terms of the relative permeability μ, with a subscript to identify the strength of the measuring field (e.g., $\mu_4 = \mu$ measured with $H = 0.4$ A/m). Starting with the unmagnetized state ($H = B = 0$), brought about either by thermal demagnetization or by an alternating field decaying to zero, the permeability increases with field strength up to the maximum permeability μ_{max}, then declines to unity as the flux density enters the magnetic saturation region.

By virtue of the relation $\mu = B/\mu_0 H$, the curve of μ versus H is derived from the "tip curve" of B versus H, which is made up of the end points of all smaller loops lying inside the largest hysteresis loop. This curve is obtained by reversing the field strength (from $+H$ to $-H$) and measuring the associated flux changes $\Delta\Phi$. It is very similar to the virgin magnetization curve (see Fig. 3).

Figure 3. Hysteresis curves $B(H)$ for various maximum driving fields H, curve of normal magnetization $B(H)$, and permeability $\mu(H)$ for a soft magnetic material

The coercive force H_c and the magnetic loss P_{Fe} are used along with the permeability μ to characterize magnetically soft materials. Because of the low field strengths, H_{cB} and H_{cJ} are not usually distinguished.

The shape of the hysteresis curve is also important. It is described as rectangular, normal, or flat (see Fig. 4) and characterized by the remanence/saturation ratio B_r/B_s.

Figure 4. Typical types of hysteresis curves
a) Rectangular; b) Normal or round; c) Flat

All the parameters of soft magnetic materials must be classified as to whether they are measured statically or dynamically. Only static measurement yields information about the pure behavior of the material.

Dynamic driving involves alternating (a.c.) fields of given frequency, amplitude and form. Induction in the soft magnetic metal gives rise to eddy currents, which degrade the magnetic parameters (see Fig. 5). Classical eddy-current theory defines a cutoff frequency f_w at which the depth of penetration of the induced field in the specimen is equal to half the specimen thickness. The effect of the associated eddy currents becomes relatively strong above this frequency.

Figure 5. Hysteresis curves of a soft magnetic material measured at four different frequencies, with otherwise identical conditions.
a) 50 Hz; b) 200 Hz; c) 400 Hz; d) 1000 Hz

The variables influencing f_w include the initial permeability μ_i and resistivity ϱ of the material and the specimen thickness D. The cutoff frequency is given by

$$f_w \approx \frac{8\varrho}{\mu_0 \mu_i D^2}$$

In order to attain a high f_w at a high initial permeability level, the material must have a high resistivity and the core shape must be such that the specimen thickness is as small as possible in the direction perpendicular to the magnetic flux. Special core geometries devised to meet this condition include wound strip cores and laminated cores with sheet thicknesses of 0.05 – 0.35 mm having electrical insulation between sheets (see Fig. 6).

The parameters of magnetically soft cores are usually measured in closed magnetic circuits, often on toroidal specimens. In this way, external effects due to the geomagnetic field or parasitic stray fields in the environment, as well as measurement errors due to shearing effects such as occur in open circuits, are eliminated. Since the coercive force does not depend on shearing, it can be quickly determined in any geometry, provided specimen saturation can be established as a reproducible initial state.

Figure 6. Typical core geometries for soft magnetic materials in dynamic applications
A) Core sheets; B) Core shapes

In dynamic measurements, the time-dependent current $I(t)$ and voltage $U(t)$ waveforms and therefore the field strength and flux density waveforms must always be taken into account, since they always have to be considered when the magnetic quantities are determined from electrical ones. In a closed magnetic circuit with a average magnetic path length l, the relation between the maximum current $\hat{I}$ and field strength $\hat{H}$ is given by

$$\hat{H} = \frac{n\hat{I}}{l} \tag{8}$$

The voltage and the flux density are related by

$$\hat{B} = \frac{1}{nA_e} \int u(t)\,\mathrm{d}t \tag{9}$$

For a sinusoidal voltage with effective value Ueff,

$$U_{\mathrm{eff}} = 4.44\hat{B}fnA_e \tag{10}$$

Efficient transformation of electrical voltages with small-cross-section A_e magnetic cores and few turns in the windings (i.e., with small inductive components) is possible if the flux density B is high at the operating point. The same result can be achieved by raising the operating frequency.

The purpose of developing improved magnetically soft materials is thus to lower the coercive force and losses and to insure a high flux density at the operating field strength.

4. Hard Magnetic Materials

Permanent magnets in industrial use can be classified as "classical" and "modern"; the classical ones are those developed up to about 1960, while the modern ones are those discovered and adopted in industry between the mid-1960s and the present. The most important of the classical materials are AlNiCo and hard ferrites. Modern materials include special rare-earth-containing alloys based on Sm−Co and Nd−Fe.

Table 1 lists the most important hard magnetic materials that have come into use since 1900. The years listed cover the time from the discovery of the material to the conclusion of the important development stages. The last two columns indicate the present importance of the materials.

From the 1800s up to the 1930s, the only materials for permanent magnets were special steels, which were "magnetically hardened" (i.e., given coercive force) by sometimes critical and costly heat-treatment processes. Tungsten, chrome and cobalt steels should be mentioned in this connection; in comparison with present-day hard magnetic materials, all of these exhibit lower stability of the permanent magnetic state. Mechanical effects, vibration, or the action of weak opposing magnetic fields irreversibly weakens the magnetic state.

An important advance in the field of permanent magnets took place in Japan in 1932, when precipitation-hardenable Al−Ni−Fe alloys were discovered [6], [7]. In the years following, these formed the basis for the AlNiCo

Table 1. Overview of hard magnetic materials in use from the early 1900s.

Material	Discovery/ development	Present-day importance	Trend
Hard magnetic steels	before 1930	important	
Cu – Ni – Fe	1935 – 1940	unimportant	
Cu – Ni – Co			
Pt – Co	1935 – 1940	minor	decreasing
V – Co – Fe	1940 – 1955	minor	decreasing
Fe – Co (ESD)	1950 – 1960	unimportant	
Cr – Fe – Co	1936 – 1960	minor	unchanged
Mn – Al – C	1958 – 1980	unimportant	
Al – Ni/AlNiCo	1932 – 1960	medium	decreasing
Hard ferrite	1950 – 1970	major	increasing
SmCo 1 : 5	1965 – 1975	major	increasing
SmCo 2 : 17	1975 – 1985	major	increasing
Nd – Fe – B	1983	medium	increasing considerably

materials, which are still of commercial importance.

Related to the AlNiCo alloys in metallography and magnetic qualities are the Cr – Fe – Co materials [8–10], which were also discovered in the mid-1930s but not industrially adopted until the beginning of the 1970s (see 4.1.1.2).

The second important group of classical hard magnetic materials are the hard ferrites. They were discovered around 1950, and developed and brought on the market between 1950 and 1960 [11], [12]. Because the raw materials are cheap and readily available and the manufacturing processes are economical, hard ferrites account for most permanent-magnet production despite their relatively low magnetic efficiency.

In addition to the AlNiCo and hard ferrite groups, a number of other materials were developed between 1930 and 1960, but these gained little commercial or industrial significance. They are listed in Table 1 and discussed in Section 4.1.3.

4.1. Classical Hard Magnetic Materials

Hard magnetic materials developed or known before 1960 include the AlNiCo group and hard ferrites, both of which are still commercially important, and also Cr – Fe – Co, Co – V – Fe, Pt – Co, Cu – Ni – Fe, Cu – Ni – Co, Mn – Al – C, and Fe – Co (ESD) materials. A few of those last named materials are still used for special applications, but their market share is shrinking.

4.1.1. Aluminum – Nickel – Cobalt Materials

Permanent magnets based on aluminum – nickel – cobalt – iron alloys, referred to as AlNiCo, form a broad spectrum of component-rich alloys with the following composition range: Al 6 – 13, Co 0 – 32, Cu 2 – 6, Ni 13 – 18, Ti 0 – 9, Nb 0 – 3 wt %, remainder Fe. Grades without cobalt, called AlNi magnets, are also available commercially; all of these have lower magnetic values. As the cobalt content increases, better values are obtained.

AlNiCo magnets are made by casting or sintering. In the casting process, the starting materials are melted in an open medium-frequency furnace and cast in sand or precision molds. In the powder-metallurgical processes, iron, cobalt, and other elements or appropriate master alloys are thoroughly mixed in powder form, shaped by compression at room temperature under a pressure of several kilobar, and sintered in an atmosphere free of oxygen and moisture either in vacuum or under an inert gas. Sinter temperatures range from 1250 to 1400 °C, depending on the alloy composition. The linear dimensions shrink by about 10 %, corresponding to an increase in density from 5 to 7 g/cm^3 during the sintering process.

Each of these processes has special features that influence the magnetic and mechanical properties of the products. Sintered magnets are finer grained than cast ones and have a uniform, cavity-free microstructure. They accordingly exhibit greater mechanical strength

than cast magnets. Furthermore, sintered magnets can be economically fabricated down to a volume of a few cubic millimeters. This possibility of making small parts is important given the present trend toward miniaturization. From the process engineering standpoint, powder-metallurgy techniques offer several further advantages over casting. Tolerances can be kept narrower, small holes and penetrations are easily made, and in general more intricate shapes can be realized.

In casting, however, controlled removal of heat during solidification makes it possible to create an oriented columnar structure in which the long direction of the grains lies preferentially close to a [100] direction of the cubic crystal lattice [13], [14]. Starting from this ordered state, excellent magnetic values in the grain axis direction can be achieved in subsequent magnetic refining.

For materials of the AlNiCo group, therefore, the selection of fabrication method is dictated by mechanical, magnetic, and economic considerations. Generally, heavy magnets are cast while lightweight ones are sintered; the boundary between these classes lies in the range 10 – 50 g. In special cases, the rule is violated; for example, rotors for high-speed motors require high strength, and although they weigh several hundred grams, they are produced by sintering. Regardless of the fabrication method, AlNiCo magnets are hard and brittle. The only way to machine them, at any stage of production, is by grinding.

After sintering or casting, the blanks have no permanent magnetic properties until they are given such properties in a multistage heat-treatment process. The cycle consists essentially of three stages, with parameters governed by the alloy composition and the type of magnet desired. A distinction is made between the production of isotropic and anisotropic magnets [15]. In anisotropic magnets, good magnetic properties are produced preferentially in one direction in space, whereas in isotropic magnets, all spatial directions are magnetically equivalent. Table 2 describes the most important steps in heat treatment.

Table 2. Heat treatment steps for AlNiCo materials

Treatment step	Isotropic magnets	Anisotropic magnets
1	Homogenization (1200 – 1300 °C)	Homogenization (1200 – 1300 °C)
2	Cooling at controlled rate to 600 °C (spinodal decomposition)	a) Cooling at controlled rate in a magnetic field (800 – 700 °C) or b) Isothermal treatment in a magnetic field near the Curie temperature (ca. 800 °C) (spinodal decomposition)
3	Tempering $T \approx 500 - 650$ °C	Tempering $T \approx 550 - 650$ °C

Figure 7. Pseudobinary Al – Ni – Co phase diagram (valid for the given composition) [20]

Understanding the processes that take place during heat treatment, requires knowledge of the phase diagram [16], [17]. Figure 7 shows the pseudobinary diagram of the Al – Ni – Co system. The dashed lines separate temperaturedependent phase regions for the compositions shown. The addition of the components shown at right and left shifts the line and thus the corresponding phase boundaries in the way indicated.

Homogenization, the first heat-treatment operation in Table 2, establishes the α-phase, which has a body-centered cubic lattice. Rapid cooling suppresses the γ-phase and freezes in theα-phase. Then, at temperatures below the $\alpha - \gamma_1$ mixedphase region, the α'-phase, which is also body-centered cubic, precipitates. This precipitation occurs by the spinodal decomposition mechanism. A highly uniform microstructure comes into being spontaneously and without the input of activation energy; the strongly magnetic, Fe – Co-rich α'-phase is present as inclusions in the weakly magnetic or nonmagnetic, Al – Ni-rich α-matrix. The shape and size of the precipitate can be controlled through temperature and time so that the finely dispersed α' inclusions are the size of magnetic single-domain particles, with transverse dimensions of ca. 10 nm and lengths of 80 – 150 nm.

It can be assumed that the single-domain particles obtained in the ideal case are remagnetized by domain rotation. For AlNiCo 700, in particular, it has been shown [18] that the experimental coercive force roughly corresponds with the value calculated from the particle composition and geometry. The hard magnetic properties of AlNiCo magnets thus bear a causal relationship to the shape anisotropy of the microstructure. The Curie temperature T_C for Al – Ni alloys is 760 °C; in AlNiCo materials, the value rises to ca. 850 °C with increasing Co content. At over 20 wt % Co (e.g., ca. 24 % Co in AlNiCo 500 or ca. 34 % Co in AlNiCo 450), the Curie temperature of the strongly magnetic α'-phase is in the region of the onset of spinodal decomposition. If phase decomposition takes place in a magnetic field, the columnar precipitates can be caused to align themselves with the field [15], [19] (each close to the nearest [100] direction of the crystallite). Depending on the alloy composition, the magnetic treatment is carried out by continuous heating in a magnetic field or by isothermal modifications of the heat-treatment procedure. In particular, high-coercivity AlNiCo materials containing titanium require finely controlled isothermal treatment in a magnetic field.

Phase decomposition in a magnetic field thus brings about an orientation with a microscopic preferential direction and leads to anisotropic magnets. The establishment of a preferential direction is especially efficient in the case of blanks with columnar grain structure when the magnetic field is parallel to the grain orientation. The best remanence and energy values are obtained in this way (see Table 3).

In tempering, the third heat-treatment operation in Table 2, the composition differences between the α- and α'-phases are heightened by diffusion processes [21], [22]. The phase-decomposition pattern, on the other hand, does not change. The coercive force is strengthened in this operation.

Table 3. Compositions and magnetic values for typical AlNiCo materials

Material designation (DIN)	Composition, wt %						Magnetic values				
	Al	Ni	Co	Cu	Ti	Fe	$(BH)_{max}$, kJ/m^3	Remanence B_r, mT	Coercive force H_{cB}, kA/m	Coercive force H_{cJ}, kA/m	Density ϱ, g/cm^3
Isotropic magnets											
AlNiCo 9/5	13	24	5	7		51	10	550	55	58	6.9
AlNiCo 12/6	11	20	15	4		50	12	600	54	58	7.1
Anisotropic magnets											
AlNiCo 35/5	9	14	24	3		50	40	1250	50	51	7.3
AlNiCo 40/12	8	14	36	3	5	34	44	880	115	120	7.3
AlNiCo 40/15	8	14	40	3	8	27	43	740	150	160	7.3
Columnar crystallized											
AlNiCo 52/6	9	14	24	3		50	62	1240	58	59	7.3
AlNiCo 80/10	8	14	40	3	8	27	80	930	150	155	7.3
Hysteresis materials											
AlNiCo 3/0.6	7	17				76	3	1000	6	6	7.1
AlNiCo 6/1.6	9	17	5			69	6	820	16	16	7.0

The many compositional variations in multicomponent AlNiCo alloys, coupled with the range of manufacturing processes, such as casting, crystallization in columnar grains, and sintering, as well as the treatment modifications leading to isotropic or anisotropic magnets, mean that there are many types of AlNiCo. About ten hard magnetic types are marketed along with several moderately hard types having intentionally low coercive force and intended for use as hysteresis materials in motors and clutches.

The isotropic, anisotropic, and columnar crystallized materials vary widely in B_r and $(BH)_{max}$ but have similar coercive forces. This comparison reflects the way in which the coercive force depends on the shape anisotropy of the precipitates, which are the same in isotropic and anisotropic qualities.

AlNiCo magnets also exhibit good temperature stability, with the remanence and coercive force being only weakly temperature dependent. The maximum service temperature of 550 °C is comparable to that of the last tempering step.

Figure 8. Typical demagnetization curves for isotropic (8/5 and 20/11) and anisotropic AlNiCo magnets
a) AlNiCo 52/6; b) AlNiCo 40/5; c) AlNiCo 40/12; d) AlNiCo 40/15; e) AlNiCo 20/11; f) AlNiCo 8/5

Figure 8 shows demagnetization curves for some isotropic and anisotropic AlNiCo magnets. Characteristic temperature data for AlNiCo magnets are listed in Table 4 along with those for other magnetic materials. The Curie temperatures for AlNiCo magnets range from 760 to 850 °C, depending on composition. The last two columns give the temperature coefficients for reversible changes in J_s or B_r and H_{cJ}. A comparison of the values with those for other materials shows that AlNiCo magnets have superior temperature stability. These properties dictate the use of AlNiCo magnets wherever high flux con-

Table 4. Characteristic temperatures for permanent magnets

Material	Curie temperature T_c, °C	Max. operating temperature, °C	$Tk(B_r)$, %/K	$Tk(H_{cJ})$, %/K
$SmCo_5$	720	250	−0.04	−0.25

Hard ferrite	450	250	−0.2	+0.40

stancy is needed, for example, in measuring instruments.

4.1.2. Chromium – Iron – Cobalt Materials

Hard magnetic Cr – Fe – Co alloys have many similarities to the AlNiCo group from metallographic and magnetophysical standpoints [23]. Chromium – iron – cobalt magnets can also be manufactured by casting or sintering. Whereas AlNiCo magnets are hard and brittle at all stages of production, the Cr – Fe – Co materials can be hot- or cold-worked at certain stages. This is the case after homogenization as well as after brief spinodal treatment. Before the final heat-treatment operations, in which the magnetic values are established, the material can be rolled, bent, punched, extruded or drawn, so that even complicated geometric forms can be fabricated. Once heat treatment is finished, Cr – Fe – Co magnets are hard and brittle. The magnetic properties are set after shaping, in a multistep heat treatment that differs in temperature range and duration from the treatment of AlNiCo magnets. A spinodal decomposition also takes place in this system, in the temperature range 600 – 700 °C, depending on alloy composition, and again an α'-phase precipitates from a high-temperature α-phase [24]. The Fe – Co-rich α'-phase forms inclusions in the chromium-rich matrix. As in the AlNiCo materials, the precipitates are anisotropic in form, and this property again forms the basis for the coercive force [25], [26]. Table 5 lists the important treatment steps for establishing the magnetic values of Cr – Fe – Co materials.

Table 5. Heat treatment steps for Cr – Fe – Co magnets

Treatment step	Isotropic magnets	Anisotropic magnets
1	Homogenization 950 – 1250 °C	Homogenization 950 – 1250 °C
2	Heat treatment 600 – 700 °C (spinodal decomposition)	Heat treatment in magnetic field at 600 – 700 °C or brief treatment at 600 – 700 °C followed by 60 – 70 % cold working (spinodal decomposition)
3	Multistep heat treatments between 600 and 700 °C	Multistep heat treatments between 600 and 700 °C

The application of a magnetic field during spinodal decomposition gives anisotropic magnets. Not only can anisotropy be introduced by magnetothermal treatment, but magnetic anisotropy in Cr – Fe – Co can also be achieved through a certain cycle of heat treatment and working. Globular precipitates are formed after brief spinodal treatment. Since the material is still ductile in this condition, the precipitates can be converted to particles with shape anisotropy by cold working (60 – 70 %) [27]. These extended phase regions are comparable in shape and effect to the columnar precipitates produced by thermomagnetic treatment.

In the final heat treatment, the concentration differences between the two phases are reinforced by diffusion processes. This leads to the generation of the coercive force. The treatment time required to set the magnetic values increases with decreasing Co content [28]. At about 23 % Co, the time for spinodal treatment and tempering is 3 – 4 h; at 3 % Co, it is ca. 150 h. Figure 9 shows schematically an entire heat-treatment cycle for Cr – Fe – Co alloys [29].

Figure 9. Progression of a Cr – Fe – Co heat-treatment cycle [29]

Figure 10. Comparison of the demagnetization curves for the Cr – Fe – Co and Al – Ni – Co alloys (columnar crystallized; magnetically tempered)
a) 24 % Cr, 15 % Co, 3 % Mo, remainder Fe (anisotropic through deformation) [29]; b) 33 % Cr, 11.5 % Co, remainder Fe [28]; c) 33 % Cr, 11.5 % Co, 2 % Cu, remainder Fe (magnetic field treatment) [28]; d) 27 % Cr, 9 % Co, remainder Fe [28]; e) AlNiCo 24 % Co, 8 % Al, 14 % Ni, 3 % Cu, remainder Fe

The composition range (in wt %) of the Cr – Fe – Co hard magnetic materials is as follows: Cr 20 – 33, Co 3 – 25, Si 0 – 3, Mo 0 – 3, Cu 0 – 3, remainder Fe.

The Cr – Fe – Co materials, both isotropic and anisotropic, have values corresponding to the middle range of AlNiCo materials. Comparable values are, however, attained in Cr – Fe – Co with significantly less Co. Table 6 summarizes the compositions and magnetic values of Cr – Fe – Co materials. For comparison, the last line describes an AlNiCo quality.

Although good magnetic values are obtained in permanent magnets with only 3 % Co, the processing times for such magnets are so long that these materials are of no commercial importance.

Figure 10 shows demagnetization curves for Cr – Fe – Co alloys and a magnetically comparable AlNiCo quality.

4.1.3. Other Metallic Hard Magnetic Materials

In addition to the AlNiCo and Cr – Fe – Co materials, a series of other metallic magnetic materials was developed in the same time period. Although these are now of little industrial importance, they are described here briefly for the sake of completeness.

Platinum – Cobalt. Hard magnetic materials based on the two-component system Pt – Co, containing 75 wt % Pt and 25 wt % Co, were developed in the mid-1930s [30]. Maximum *BH* values of ca. 80 kJ/m^3 at a coercive field strength of 50 kA/m (Table 7) were obtained after heat treatment at 600 – 1000 °C with controlled cooling, during which a two-phase structure consisting of a face-centered cubic and a tetragonal phase is formed. Due to the high cost of Pt – Co, it was used for small or very small magnets such as those in hearing aids and watches. Today, Sm – Co magnets are used for these applications. The high corrosion resistance of Pt – Co led to its use in medical technology.

Cobalt – Vanadium – Iron. Magnetic materials containing 50 wt % Co, 7 – 15 wt % V, and the remainder Fe were developed in the 1940s [31]; 3 – 5 % of the vanadium can be replaced by chromium [32]. These alloys were known as vicalloy. The material can be worked by cold rolling or drawing before the magnetic values have been established. Since a cold-working grade of ca. 90 % is required for optimum hard magnetic properties to be attained, only wires with a maximum diameter of 3 mm and ribbons with a maximum thickness of 0.6 mm can be produced. After cold rolling or drawing, the material can be formed by stamping, cutting, and bending. However, the high tensile strength limits the extent to which it can be bent and the

Table 6. Overview of the composition and magnetic values of anisotropic Cr – Fe – Co magnets

Composition, wt %						
Co	Cr	Fe	Additives	B_r, mT	H_{cB}, kA/m	$(BH)_{max}$, kJ/m^3

Co – Fe (ESD)	anisotropic	1050	75	77	50
Mn – Al – C	anisotropic	580	220	250	52

size of the holes that can be stamped. After forming, the magnetic values are established in a final heat-treatment process at 530 – 620 °C, during which part of the ferromagnetic phase transforms to a nonferromagnetic phase, and the magnetically easy direction rotates through 90° towards the rolling or drawing direction. This treatment also greatly increases the hardness of the alloy, so that it can then only be worked by cutting and grinding. The magnetic properties of these alloys are listed in Table 7.

Copper – Nickel – Iron and Copper – Nickel – Cobalt. The hard magnetic properties of the three-component system Cu – Ni – Fe, with the composition 60 % Cu, 20 % Ni, and 20 % Fe, were discovered in the 1930s [33]. Due to the presence of a strongly temperature dependent miscibility gap in the Cu – Ni – Fe system, the precipitation of an Fe – Ni-rich phase from the copper-rich matrix can be controlled by heat treatment, after the material has been homogenized at 1040 °C, quenched, and heat treated at 650 °C. This procedure gives anisotropic magnets [34]. Short tempering of the alloy at 650 °C, followed by 90 – 95 % cold forming and heat treatment at 650 °C establishes a magnetically easy direction in the direction of working [35]. Magnetically isotropic and anisotropic Cu – Ni – Fe materials are listed in Table 7. The Cu – Ni – Co magnets did not gain industrial importance.

ESD Magnets. The idea behind elongated-single- domain (ESD) materials was to prepare highly shape anisotropic powder particles from alloys with high saturation magnetization. Elongated-single- domain particles can be prepared from iron or iron – cobalt salts at room temperature by means of a mercury electrode [36], [37]. The resulting fine particles are enlarged by brief heat treatment at 100 – 200 °C, and traces of mercury are removed. The powder is converted to anisotropic magnets by compression in an orienting magnetic field, with addition of tin, antimony, or lead as a binding agent. Further heat treatment or mechanical working of the pressed magnets is not necessary. The ESD magnets, which were used for many years in the United States under the trade name Lodex, are now only of historical importance. Magnetic values are listed in Table 7.

Manganese – Aluminum – Carbon. The nonferromagnetic elements manganese and aluminum form a ferromagnetic $\bar{l}$-phase (69 – 75 wt % Mn, remainder Al) [38]. The tetragonal $\bar{l}$-phase is formed from a hexagonal high-temperature phase by cooling from 1000 °C at a rate of 350 – 780 °C/min. This $\bar{l}$-phase exhibits

a uniaxial magnetic anisotropy and has a Curie temperature of 300 °C. The addition of 0.4 – 1 wt % carbon increases the stability of the ferromagnetic phase from 400 °C to 700 °C. In the 1970s anisotropic Mn – Al – C magnets with good mechanical and magnetic properties were obtained by heat treatment at 650 – 750 °C with 60 – 70 % reduction in cross-sectional area [39], [40]. Despite the cheap raw materials and the good magnetic values, these materials failed to gain industrial importance because of the complex production process [41]. The magnetic values are listed in Table 7.

4.1.4. Hard Ferrites

Hard ferrites form a group of ceramic permanent-magnet materials based on phases $MFe_{12}O_{19}$ (where M = Ba, Sr, Pb) and solid solutions of these such as $Ba_{1-x}Sr_xFe_{12}O_{19}$. The barium and strontium ferrites have found industrial use, while lead ferrites are not manufactured for reasons of toxicity.

The name hard ferrite results from the ability of these materials to generate high coercive forces that can be reproducibly set under optimized production conditions. As ceramics, hard ferrites exhibit high mechanical hardness and are brittle and very susceptible to fracturing.

Hard ferrites crystallize in the hexagonal magnetoplumbite structure. The crystal lattice exhibits hexagonal close sphere packing for the oxygen ions as well as the barium and strontium ions, while the smaller iron ions occupy interstitial positions. The unit cell of this ferrite lattice contains two barium or strontium ions, 24 iron, and 38 oxygen, and thus includes two $Ba/Sr \cdot Fe_{12}O_{19}$ formula units. The theoretical densities of barium and strontium ferrites, calculated from the unit cell, are $\varrho = 5.28$ and 5.10 g/cm^3, respectively.

Hard ferrites exhibit uniaxial magnetic crystal anisotropy. Magnetic polarization spontaneously takes up the direction of the crystallographic *c* axis. The resulting large crystal anisotropy constant is the basis for the high coercive forces realized with these magnetic materials (see Section 4.2.1, Eq. 11). The crystal anisotropy constants, saturation polarizations, anisotropy field strengths H_A, and the coercive forces achieved are summarized in Table 8. As in the rare earth permanent magnets (see Section 4.2.1) defects and inhomogeneities mean that hard ferrites can reach only ca. 20 % of the theoretical coercive force H_A.

Table 8. Anisotropy constant K_1, H_A, H_{cJ} and J_s values for hard ferrites [44]

	K_1, kJ/m^3	H_A, MA/m	J_s, mT	H_{cJ}, kA/m
$Ba\,0 \cdot 6 \cdot Fe_2O_3$	300	1.34	460	150 – 350
$Sr\,0 \cdot 6 \cdot Fe_2O_3$	346	1.45	472	150 – 350
$Pb\,0 \cdot 6 \cdot Fe_2O_3$	220	1.13	464	

The carrier of the magnetic polarization of hard ferrites is iron. Trivalent iron ions located at five nonequivalent lattice sites couple antiferromagnetically via oxygen bridges. Because of partial compensation of the magnetic moments of the iron ions, hard ferrites exhibit a magnetic saturation polarization that is low in comparison with other hard magnetic materials [42] (see Table 9). On average, this ferrimagnetic coupling leaves only one of three magnetic moments with any external effect. High-quality anisotropic hard ferrites with remanences of 440 – 450 mT achieve 93 – 95 % of the theoretical saturation polarization.

Hard ferrites are made by powder sintering or with resin binders [43]. The essential steps in the manufacturing process are reaction sintering, grinding, molding of the powder into compacts, sintering, and mechanical finishing of the sintered articles if necessary.

Barium and strontium ferrites are produced by heating a mixture of the corresponding carbonate with iron(III) oxide at 1200 °C.

$$MCO_3 + 6\,Fe_2O_3 \rightarrow MO \cdot 6\,Fe_2O_3 + CO_2$$

Details of this multistage reaction process can be found in the literature [44].

Low contents of SiO_2 and Al_2O_3 do not cause difficulties, since small quantities of these substances are frequently added on purpose to control sintering behavior (SiO_2) and increase the coercive force (Al_2O_3). Optimal magnetic values are obtained when the Ba or Sr content is increased to a molar ratio of ca. 1 : 5.6.

The compounds formed in reaction sintering are ground in ball or attritor mills, with water as grinding medium, to yield powders with particle sizes ≤ 1 µm. In the manufacture of high-quality hard ferrites, it is very important to achieve a

Table 9. Magnetic values for hard ferrite sinter and injection-molded magnets

Material	Isotropic or anisotropic	B_r, mT	H_{cB}, kA/m	H_{cJ}, kA/m	$(BH)_{max}$, kA/m^3	Density, g/cm^3
Sinter magnets						
Hard ferrite 8/27	isotropic	230	155	290	9	~4.9
Hard ferrite 24/35	anisotropic	360	260	350	24	~4.9
Hard ferrite 32/25	anisotropic	410	240	250	32	~4.9
Hard ferrite 32/17	anisotropic	410	160	165	32	~4.9
Injection-molded magnets						
Hard ferrite 1/18 P	isotropic	80	60	170	1.0	~2.9
Hard ferrite 8/19 P	anisotropic	120	80	200	8.0	~3.5
Hard ferrite 12/12 P	anisotropic	250	180	220	12.0	~3.5

narrow, reproducible particle-size distribution in which the single- crystal particles are the size of single magnetic domains. Both the coercive force and the remanence depend on this point.

In the next step, the ferrite powder is molded, wet or dry, at pressures of 100 – 300 MPa, into compacts with densities of 3.3 – 3.5 g/cm^3. If an orienting magnetic field of 200 – 400 kA/m is imposed during compaction, the single-crystal particles line up parallel to the field [12]. This orientation is fixed by compaction and is not disrupted in sintering. In this way, anisotropic magnets with a distinct easy direction are obtained. Wet compaction, with 28 – 35 % water added to the mixture, gives the best alignment of powder particles in the compacts. Much of this water is expelled on compression. Both isotropic and anisotropic ferrite magnets of medium quality are made by the compaction of dry powders.

The compacts are sintered in air at 1150 – 1250 °C in continuous tube furnaces; the coercive force and remanence can be controlled within certain limits by varying the sintering parameters. The density increases in sintering, ultimately reaching 95 – 98 % of the theoretical material density. The linear contraction on sintering is ca. 16 % for isotropic magnets, while for anisotropic magnets, it is ca. 22 % parallel to the easy direction and ca. 13 % perpendicular to the easy direction. Hard ferrites do not require further heat treatment to set or optimize the magnetic values after sintering. The last step in production is grinding if the dimensional tolerances make this necessary.

Along with sintered magnets, resin-bonded ferrite magnets (plastoferrites) have also become economically and industrially important [44], [45]. These magnets are produced by mixing hard ferrite powders with, for example, rubber, poly(vinyl chloride), polyamide, or resins. This operation takes place in a mixer, mixer-extruder, or kneader. Rolling and injection molding or compression molding follow. Anisotropic magnets can be produced by injection molding and compression molding if orienting magnetic fields are imposed.

Depending on the production process, plastoferrites with various filler contents can be made. Injection molding makes it possible to obtain isotropic and anisotropic magnets with ferrite powder contents of 50 – 65 vol %; isotropic magnets made by injection molding or rolling contain up to 70 vol% filler, and compression-molded articles up to 80 vol %.

The reduction in magnetic values due to the lower volume fraction of the magnetic phase in resin-bonded magnets is offset by a number of technical and economic advantages. For example, plastoferrites have much better mechanical properties than brittle sintered magnets because of their elasticity and toughness. These properties, as well as the other physical and chemical properties, depend on the magnetic material as well as the filler content.

Improved mechanical properties offer substantial advantages for subsequent processing. The higher stability of the edges permits automatic handling of the magnets during assembly. The toughness of composite materials in conjunction with the close tolerances that are possible with injection molding makes it possible to use interference fits for attaching magnets to other components. By virtue of high edge strength and easy, high-precision fabrication of complicated shapes without finishing treatment, product costs can be held down and, in many cases, new products can be realized. The mechanical properties and manufacturing ad-

vantages of resin-bonded hard ferrites set them above all competing hard magnetic materials in applications where their relatively low magnetic level can be accepted.

Table 9 summarizes typical magnetic values for isotropic and anisotropic sintered and resin-bonded ferrites. The values in the table are for room temperature. Figure 11 shows demagnetization curves for isotropic and anisotropic hard ferrites.

Figure 11. Demagnetization curves for hard ferrites; 8/27 isotropic, remainder anisotropic
a) Hard ferrite 26/29; b) Hard ferrite 32/26; c) Hard ferrite 26/29; d) Hard ferrite 8/27; e) Hard ferrite 28/15

The magnetic values of hard ferrites depend strongly on the temperature. In addition, the temperature variations of remanence and coercive force have opposite signs. Typical temperature data and temperature coefficients for hard ferrites are listed in Table 4.

4.2. Modern Hard Magnetic Materials

The development of hard magnetic materials with rare earth elements (RE) as essential components began in the mid-1960s and has yielded three groups of materials with magnetic values several times greater than those of classical AlNiCo and hard-ferrite magnets.

The $RECo_5$ magnets were the first generation of these materials [46], [47]. Of these, $SmCo_5$ is the magnetic material of greatest commercial and industrial significance today.

At the beginning of the 1970s, development started on a second generation of magnetic alloys based on rare earth elements and cobalt. These are multicomponent alloys containing not only rare earth elements and Co but also Cu, Fe, and alternatively Ti, Zr, or Hf [48–50]. The samarium-based alloys are most important in this group as well. As Table 11 shows, these materials contain ca. 10 % less Sm and ca. 15 % less Co than does $SmCo_5$.

The most recent group of rare earth hard magnetic materials are based on neodymium – iron – boron; these magnets were developed in 1983 in Japan [51] and the United States [52]. Their magnetic values surpass those of all other hard magnetic materials.

Figure 12 presents figures characterizing the quality of classical and modern hard magnetic materials: the energy product as a measure of magnetic performance and the coercive force as a measure of magnetic stability. The comparison makes clear the superiority of modern materials. The years listed mark the beginning of industrial production in each case. The rising trend in magnetic values has led to both smaller magnet systems and also new applications for permanent magnets.

Figure 12. Hard magnetic material values (the year denotes the beginning of the industrial application)

The assessment of a hard magnetic material from the economic standpoint depends on not only the magnetic properties but also the availability and cost of raw materials and the reliability of supplies. In view of these points, Nd – Fe – B materials are much more promising than the Sm – Co group [53].

The most important rare earth elements for the manufacture of high-quality permanent

magnets, samarium and neodymium, occur in markedly different concentrations in ores. The abundance of Nd is 7 – 16 times greater than that of Sm. While ca. 350 t of Sm_2O_3 is available at present, enough for ca. 1000 t of Sm – Co magnets, current forecasts are that capacity increases will make 4000 – 5000 t/a of Nd available in the near future, enough to make more than 10 000 t of Nd – Fe – B magnets.

Rare earth permanent magnets based on Sm – Co and Nd – Fe – B are manufactured by powder sintering [54]. Other process variants exist for the production of Nd – Fe – B magnets; these are described in Section 4.2.2.

Figure 13. Flow sheet for the production of rare earth permanent magnets

The essential steps in the powder-metallurgical production process are illustrated in Figure 13. First the alloys are prepared. Two processes are used: melt-metallurgical production from the elements or master alloys, and preparation of the alloys by a reduction and diffusion process (co-reduction). The co-reduction process starts with oxides of the rare earth metals, such as Sm_2O_3 or Nd_2O_3, which are thoroughly mixed with the other alloy constituents and calcium in powder form and are then reduced by the calcium in reactors at ca. 1100 °C [55–57]. The desired alloys are formed directly in this process. The resulting powders, with particle sizes of $\leq 200\,\mu m$, are then fine ground, after the calcium has been washed out. Materials prepared by the melt-metallurgical technique, on the other hand, must first be precrushed and preground. In the case of Nd – Fe – B alloys produced by melt metallurgy (Section 4.2.2), the ingot can be disintegrated by hydrogenation [58]. To initiate this process it is sufficient to expose the material at room temperature to a hydrogen atmosphere of a few hundred millibar. The alloy absorbs hydrogen in an exothermic reaction, and the ingot disintegrates into particles smaller than 100 µm. In this way a powder suitable as fine-grinding feed is obtained, and a high grinding throughput is insured.

Fine grinding of the alloys takes place in ball, attritor, or opposed-jet mills. The mean particle sizes after grinding are 4 – 5 µm for Sm – Co materials and 3 – 4 µm for Nd – Fe – B; in either case, the goal is to obtain single-crystal particles.

Single-crystal powders are charged into the cavity of a press die and pressed into compacts in the presence of a magnetic field, or else they are isostatically compacted, also with a field. The magnetically anisotropic powder particles align with the direction of the applied magnetic field. This orientation is fixed by the compacting action.

Sintering is carried out under vacuum or an inert atmosphere at 1050 – 1200 °C, depending on the material. Between 16 and 20 % shrinkage occurs during sintering. Heat treatments as appropriate to the alloys are carried out afterward in order to produce a microstructure favorable for the coercive force (see Sections 4.2.1 and 4.2.2).

Because the fine-grained alloy powders have a strong affinity for oxygen, grinding, pressing, and sintering, and the handling of the powder and compacts between these operations must be performed under an inert atmosphere.

After heat treatment, the magnets are ground if necessary to meet tolerances. Larger blocks of materials can be cut into smaller parts. Magnets weighing as little as 0.1 g are not a rarity.

4.2.1. Rare Earth Metal – Cobalt Magnets

A number of binary and multicomponent RE – Co materials, with distinct uniaxial magnetic anisotropy, high saturation anisotropy, and a high Curie temperature, satisfy the essential requirements for the fabrication of high-quality permanent magnets.

Figure 14 shows the binary phase diagram for the Co – Sm system [59]. The striking point is the great number of compounds, some of which occur in very small ranges. The 1 : 5 compounds decompose, below certain system-dependent temperatures, into the equilibrium phases existing at those temperatures. Below 800 °C, $SmCo_5$ decomposes into the Sm_2Co_{17} and Sm_2Co_7 phases. However, rapid cooling from 800 to ca. 400 °C insures the existence of $SmCo_5$ as a metastable phase below 400 °C.

Figure 14. Phase diagram of the Sm – Co system

The phase diagrams for the other RE – transition-metal systems are very similar to the Co – Sm diagram, though not all the systems display identical compositions; for example, the compound $SmFe_5$ does not exist.

Figure 15 shows the saturation polarization for the $RECo_5$, $(RE)_2Co_{17}$, $(RE)_2Fe_{17}$ and $(RE)_2Fe_{14}B$ groups [60], the last of which is the crucial phase in Nd – Fe – B magnets (Section 4.2.2). The light metals from Ce to Sm become ferromagnetically coupled with the transition metals Co and Fe; hence these compounds exhibit a high saturation polarization. In contrast, the heavy rare earth metals from Eu to Lu couple antiparallel to the transition metal moments, so that some of these compounds have very low saturation polarizations.

Figure 15. Saturation polarization J_s of $RECo_5$, $(RE)_2Co_{17}$, $(RE)_2Fe_{17}$, and $(RE)_2Fe_{14}B$ at room temperature

Figure 16 gives plots of Curie temperature for the compounds $RECo_5$, $(RE)_2Co_{17}$, $(RE)_2Fe_{17}$ and $(RE)_2Fe_{14}B$ [60]. The rare earth elements exhibit only very weak magnetic ordering and so have low Curie temperatures. Gadolinium has the highest Curie temperature of the whole group (T_C= 16 °C).

When the transition metals Ni, Fe, and Co – with respective Curie temperatures of 358, 768 and 1121 °C – combine with rare earth metals, the strong magnetic coupling of the 3 *d* electrons in the former is imposed on the latter through a pronounced 4 *f* – 3 *d* interaction.

The 1 : 5 compounds crystallize in a hexagonal structure of the $CaCu_5$ type. The 2 : 17 compounds occur in two uniaxial structural modifications, one hexagonal of Th_2Ni_{17} type, and one rhombohedral of Th_2Zn_{17} type (see Fig. 17) [61], [62]. The relationship of these to the 1 : 5 structure can be seen in the fact that both modifications can be built up by combining structural elements of the 1 : 5 lattice.

With the uniaxial magnetocrystalline anisotropy in the hexagonal or rhombohedral

lattice, the polarization vector points in the direction of the crystallographic c axis. This is the case in nearly all 1 : 5 compounds, at least at room temperature. In the binary 2 : 17 alloys, however, uniaxial anisotropy is the exception rather than the rule; the polarization is usually perpendicular to the hexagonal or rhombohedral axis. The polarization is free to rotate in the plane, meaning that high coercive forces cannot be achieved [63].

Figure 16. Curie temperature T_c for $(RE)_2Co_{17}$, $(RE)_2Co_5$, $(RE)_2Fe_{17}$, and $(RE)_2Fe_{14}B$

In many 2 : 17 compounds, the inclusion of various elements makes it possible to convert the planar anisotropy to uniaxial. Other potential hard magnetic alloys can be obtained in this way. Figure 18 shows how the direction of anisotropy depends on composition for several ternary 2 : 17 systems [60].

Figure 17. Structures of the 1 : 5 and 2 : 17 compounds
Big circle: = Rare earth atom; Hatched circle, Small circle = Cobalt or a metal atom

The magnitude of the magnetocrystalline anisotropy is expressed in the anisotropy constant K_1, which is positive for uniaxial and negative for planar anisotropy. The anisotropy constant is a measure of the work per unit volume that must be done to rotate the magnetic polarization from the preferential direction it assumes spontaneously (easy direction) into the direction perpendicular to it (difficult direction); for uniaxial anisotropy in the hexagonal lattice, this means from the c direction into the basal plane.

In the case of uniaxial anisotropy, the maximum possible coercive force or the anisotropy field strength H_A can be calculated from K_1 and the saturation polarization J_s [86]:

$$H_A = \frac{2K_1}{J_s} \tag{11}$$

Table 10 lists values of J_s and H_A for several 1 : 5 and 2 : 17 combinations. The large H_A of 31 MA/m for $SmCo_5$ and the comparatively small H_A of 6.8 MA/m for Sm_2Co_{17} are noteworthy [64–68].

Hatched = Easy plane; Horizontally striped = Easy axis; Plane = Mixed phases or unknown

Table 10. J_s and H_A values for some 1 : 5 and 2 : 17 material combinations [54]

Composition	J_s, T	H_A, MA/m
YCo_5	1.06	10.4
$LaCo_5$	0.91	14.0
$CeCo_5$	0.85	12.5
$PrCo_5$	1.20	13.9
$SmCo_5$	1.12	31.0
Sm_2Co_{17}	1.28	6.8
$Sm(Co, Cu)_{7.8}$	1.09	6.1
$Sm(Co, Fe)_{8.5}$	1.46	4.7

The coercive force H_c corresponding to H_A is found for the ideal case of a reversal of the magnetization by means of a coherent rotation of the polarization vectors. For real crystals with their various imperfections and inhomogeneities, however, this mechanism is not applicable. Remagnetization under the action of external fields generally occurs by nucleation of domain walls and their movement through the crystal, or else when walls already present break free from their positions and move. In the first case, the resulting coercive force is the field that can generate remagnetization nuclei and cause domain walls to move; in the second case, it is the field that can release domain walls from their pinning centers and shift them [54].

In real materials, the coercive force is governed by the resistance to domain-wall formation and/or the force pinning the existing walls and thus preventing their movement. The coercive forces of magnetic polarization produced by these mechanisms have been found to be of the order of $H_{cJ} < 0.3\,H_A$.

Both mechanisms – nucleation and pinning – occur in the RECo group of hard magnetic alloys, depending on composition. The nucleation mechanism governs H_{cJ} in the $RECo_5$ and the single-phase $RECo_{8-8.5}$ materials. These are built up from single-domain particles, and the grain walls hinder the movement of domain walls from grain to grain.

The virgin magnetization curves for materials with the nucleation mechanism rise steeply as a function of the magnetizing field strength, reaching the saturation polarization at relatively low fields. Obviously, domain walls are being completely displaced from the grain volume, against no great resistance, or else pinned fast in surface zones. Curve (a) in Figure 19 is the virgin curve for an $SmCo_5$ magnet [69].

Figure 19. Virgin magnetization curves for 1 : 5 and various 2 : 17 magnets [54]
a) $SmCo_5$; b) $Sm(Co, Fe, Cu, Zr, Ti)_7$ low coercivity; c) $Sm(Co, Fe, Cu, Hf)_7$; d) $Sm(Co, Fe, Cu, Zr)_{7.5}$ high coercivity

In 1 : 5 and 2 : 17 alloys with copper, having compositions of $Sm(Co, Cu)_5$ and $Sm(Co, Cu, Fe, M)_{6.8-7.6}$ (M = Zr, Hf, Ti), the pinning mechanism determines H_{cJ}. Since the $Sm(Co, Cu)_5$ alloys are of no industrial significance because of their relative low magnetic values (see Table 11), the discussion that follows will center on 2 : 17 alloy types containing copper.

Figure 20. Precipitation microstructure of low- and high-coercivity Sm(Co, Cu, Fe, Zr) 2 : 17 alloys
A) Low coercivity; B) High coercivity

In the course of a composition-dependent heat treatment, the $Sm(Co, Cu, Fe, M)_{6.8-7.6}$ alloys (M = Zr, Hf, Ti, etc.) form a two-phase microstructure with a cobalt- and copper-rich matrix having the 2 : 17 structure and coherent precipitates of a copper-rich phase with the 1 : 5 structure. This two-phase structure, in which the phases differ with respect to saturation polarization and anisotropy, is responsible for the pinning of the domain walls.

Figure 20 shows transmission electron micrographs of the two-phase structure for alloys with markedly different coercive forces: Figure 20 A is for an $Sm(Co, Cu, Fe, Zr)_{6.8}$ alloy with $H_{cJ} \approx 560$ kA/m, and Figure 20 B is for an Sm-(Co, Cu, Fe, Zr)$_{7.5}$ alloy with $H_{cJ} > 1800$ kA/m. The cell diameters of the 2 : 17 phases are 40 – 60 nm in the first case and 100 – 120 nm in the second. For a quantitative understanding of the relationship between precipitate particle size and precipitate structure, see [70], [71].

The submicroscopic picture of the magnetically hardenable SmCo two-phase structure is very similar to the microstructure of AlNiCo and Cr – Fe – Co alloys in the magnetically optimized condition. The principal difference is the type of anisotropy. In AlNiCo alloys, for example, strongly magnetic Fe – Co-rich particles with shape anisotropy are created in a weakly magnetic Ni – Al-rich matrix; in the RE – Co alloys, strongly magnetic, crystallographically anisotropic zones are surrounded by weakly magnetic or nonmagnetic copper-rich phases.

Figure 19 shows the virgin curves of 2 : 17 alloys having low and high coercive force. The shape of the virgin curves for the precipitation-hardened 2 : 17 materials is quite different from that for $SmCo_5$ [54]. The low-coercivity 2 : 17 compounds show a rapid increase of polarization in magnetizing fields of the order of their H_{cJ} values. The polarization of the high-coercivity 2 : 17 alloy increases relatively slowly up to fields of about 2500 kA/m and does not begin to rise sharply until the range of 3000 – 4000 kA/m [54].

The various mechanisms responsible for generating the coercive force are manifest not only in the virgin curves but also in the demagnetization curve (plotted versus magnetizing field strength).

At magnetizing fields as low as 800 – 1000 kA/m, $SmCo_5$ magnets reach ca. 99 % of their remanence. The formation of the coercive force, however, requires fields of 2400 – 3000 kA/m. Only the action of these fields leads to the removal of domain walls out of the grains or their pinning in surface zones.

Low- coercivity 2 : 17 magnets with H_{cJ} values of 500 – 800 kA/m require field strengths of ca. 1000 – 1500 kA/m for complete magnetization, whereas high-coercivity 2 : 17 materials with coercive forces > 2000 kA/m require fields of ≥ 4000 kA/m for magnetization. The effect of magnetizing field strength on the shape of the demagnetization curve is shown in Figure 21 for $SmCo_5$ and high-coercivity 2 : 17 magnets. The

poor magnetizability of the latter leads to problems where, for reasons of manufacturing technology, the parts are not magnetized until they have been installed in the system. In most cases, the required magnetizing devices are not available. Magnetization at elevated temperature (see Fig. 22) makes possible a significant reduction in the field strength required for complete magnetization. This dependence is utilized in some instances.

Figure 21. Effect of the magnetizing field strength on the demagnetization curves of 1 : 5 magnets and high-coercivity 2 : 17 magnets
a) 2 : 17, $H = 4800$ kA/m; b) 2 : 17, $H = 1000$ kA/m; c) 1 : 5, $H = 2800$ kA/m; d) 1 : 5, $H = 1000$ kA/m

Figure 22. Dependence of remanence B_r on magnetic field strength and temperature [54]
a) Magnetized at room temperature; b) Magnetized at 200 °C; c) Magnetized at 400 °C

Table 11 gives a representative summary of the compositions and magnetic values for RE–Co hard magnetic materials. The 2 : 17 magnets contain ca. 10 % less samarium and 15 % less cobalt than $SmCo_5$, while the B_r and $(BH)_{max}$ values are higher.

Characteristic temperature data for $SmCo_5$ and 2 : 17 SmCo magnets appear in Table 4. As the temperature rises, 2 : 17 magnets display smaller magnetization losses than $SmCo_5$, and their maximum service temperature is also higher. The long-term thermal stability, measured by the relative flux loss at room temperature after holding at 200 and 300 °C, is illustrated by Fig. 23 [41], [54].

Figure 23. Comparison of the long-term thermal stability of 1 : 5 and 2 : 17 magnets
– – – = 1 : 5 magnets; —·— = 2 : 17 magnets; B_A = relative residual flux density; t = ageing time $B/\mu_0 H = -1$

In limited temperature ranges, the temperature coefficients of remanence Tk (J_s) for SmCo magnets can be reduced to ca. −0.002 to +0.002 %/K by the addition of small amounts of heavy rare earth metals [72], [73].

Besides sintered magnets, SmCo materials are also available in resin-bonded modifications (as are hard ferrites). These can be fabricated by injection or compression molding. The materials have maximum service temperatures of 80–100 °C (resin-bonded $SmCo_5$) and 120–140 °C (resin-bonded 2 : 17 SmCo).

4.2.2. Rare Earth Metal – Iron – Boron Magnets

Essential in permanent magnets based on RE–Fe–B is a tetragonal phase of composition $(RE)_2Fe_{14}B$, which exhibits a marked uniaxial magnetic crystal anisotropy for a number of rare earth elements (Table 12) [74], [75]. As in the case of samarium–cobalt materials, this anisotropy is responsible for the coercive force. The relationships between the crystal anisotropy, the saturation polarization, and the maximum possible coercive force (anisotropy field strength H_A) are analogous to those discussed in Section 4.2.1.

Table 11. Composition and magnetic values for rare earth (RE) – Co permanent magnets

Material	Typical composition, wt %								Typical magnetic values			
	Sm	Pr	MM∗	Co	Fe	Cu	Zr	Resin	$(BH)_{max}$, kJ/m^3	B_r, mT	H_{cB}, kA/m	H_{cJ}, kA/m
$(Sm_{0.2}MM_8)Co_5$	7		27	66					120	800	580	1000
$(Sm_{0.4}Pr_{0.6})Co_5$	16	18		66					200	1050	720	1200
$Sm(CoCuFe)_5$	34			49	5	12			110	770	290	300
$SmCo_5$	34			66					160	920	680	2500
$Sm(Co, Cu, Fe, Zr)_{6.9}$	24 – 26			48 – 50	10 – 16	5 – 12	1.5 – 3		240	1130	540	580
$Sm(Co, Cu, Fe, Zr)_{7.5}$	24 – 26			48 – 50	10 – 16	5 – 12	1.5 – 3		210	1080	780	800
$SmCo_5$ (resin bonded)	33		62					2.5	110	760	580	1000

∗ Misch metal (cerium-rich rare earth mixture)

Table 12. Anisotropy constant K_1, saturation polarization J_s, anisotropy field strength H_A, and Curie temperature for several $(RE)_2Fe_{14}B$ compounds [75]

$(RE)_2Fe_{14}B$	K_1, MJ/m^3	J_s, mT	H_A, kA/m	T_c, °C
Ce	1.7	1.17	2069	262
Pr	5.6	1.56	5970	294
Nd	5.0	1.60	5970	317
Dy	4.5	0.71		322
Ho	2.5	0.81	7320	303

Figures 15 and 16 show the saturation polarization J_s and the Curie temperature T_C for $(RE)_2Fe_{14}B$ compounds as functions of the RE component. As in the case of RECo, light RE elements couple ferromagnetically with transition metals and so exhibit higher saturation polarizations than the ferrimagnetically coupling heavy RE elements. Neodymium – iron – boron, the material in this series that has gained the greatest technical and economic importance, has J_s= 1.6 T, substantially higher than the saturation polarizations of $SmCo_5$ (1.07 T) and Sm_2Co_{17} (1.2 T).

The Nd – Fe – B permanent magnets became known in 1983 after parallel but independent development in Japan and the United States [51], [52]. A variety of processes are used for production of magnets.

The process developed in Japan involves powder sintering. The sequence of operations is similar to that for Sm – Co magnets (cf. Fig. 13). Nd – Fe – B alloys are prepared by melt metallurgy from the elements or prealloys (e.g., Nd – Fe), or by co-reduction with oxides (Nd_2O_3) and Ca as reducing agent. The alloys are then ground in ball, attritor, or opposed-jet mills; the product is a single-crystal powder with a mean particle size of 3 – 4 µm [56], [57]. The powder is compacted under an imposed magnetic field, and the compacts are sintered in vacuum or under an inert atmosphere. The optimal magnetic values are set in a subsequent heat treatment. The grinding process can be made much more efficient if the materials are embrittled by hydrogen absorption; the hydrogen is liberated again at temperatures of 200 – 700 °C in the sintering process [58].

The Nd content of Nd – Fe – B magnets is 31 – 34 wt %, higher than the 26.7 wt % Nd in the compound $Nd_2Fe_{14}B$. The magnets thus contain not only the dominant 2 : 14 : 1 compound but also other phases, such as $NdFe_4B_4$ and Nd-rich phases, which are important for sintering (sintering aids) and also for imposing the coercive force. The Nd – Fe – B powders have a higher oxygen affinity than the Sm – Co materials, so that even greater care and caution are necessary in the handling of the powders during the production process.

In the Nd – Fe – B magnet process developed in the United States, the alloys are produced by rapid quenching [52]. When molten alloys are quenched at cooling rates of 10^5 – 10^6 K/s, an amorphous or microcrystalline material is obtained; tempering converts this to a homogeneous microstructure. The polycrystalline, tinsel-like ribbon obtained in this process (30 – 50 µm thick and ca. 2 mm wide) is briefly ground to 200 µm. The powder particles consist of an agglomerate of isotropically distributed single crystals 15 – 150 nm in size.

Isotropic or anisotropic Nd – Fe – B magnets can be made from these materials by a variety of methods. Isotropic plastic-bonded Nd – Fe – B magnets are fabricated by injection molding

with a thermoplastic binder or by compression molding with an epoxy binder. Although these magnets have markedly lower magnetic values than anisotropic sintered magnets (see Fig. 12) because of their isotropy and the dilution of the magnetic material, they exhibit a number of advantages similar to those of plastoferrites. The simple fabrication technique, offering close tolerances and requiring no subsequent mechanical working, and the significantly lower brittleness, in comparison with sintered magnets, mean that resin-bonded Nd – Fe – B magnets are a technically and economically interesting approach for many applications.

The melt-spun material can be processed into compact isotropic magnets by hot-press molding at temperatures between 650 and 750 °C [76]. These have higher magnetic values than the resin-bonded composites discussed above.

Finally, plastic deformation of the isotropic compact magnets at ca. 700 °C produces a texture associated with a magnetic anisotropy [76], [77]. The magnetic values so achieved are comparable with those of anisotropic sintered magnets.

Other processes for making Nd – Fe – B alloys and magnets are now in the laboratory and pilot-plant stage. A mechanical alloying technique [78] begins with the starting materials neodymium, iron, and boron, in elemental form or as prealloys. These are intensively ground in ball or attritor mills, then subjected to a brief reaction anneal. Finely divided crystalline $Nd_2Fe_{14}B$ powders are obtained. Isotropic magnets can be produced by hot-press molding of these powders; anisotropic ones, by subsequent cold extrusion. The properties are comparable with those of magnets produced from melt-spun powders.

In melt-spraying techniques, such as the Ospray process [79] or liquid dynamic compaction (LDC) [80], melts are atomized in a gas stream and deposited on cooled substrates. Isotropic magnetic Nd – Fe – B layers with grain sizes of 1 – 20 µm are obtained. The remanence values are ca. 650 mT and the coercive forces up to 800 kA/m.

The high cost and delicacy of processing oxidation-sensitive Nd – Fe – B alloys in powder-metallurgical methods of magnet production has led to a search for alternatives. One such process involves subjecting ingots to special cold extrusion and cold upsetting treatments [81]: textures with a preferred magnetic direction result. This method is particularly successful with praseodymium – iron – boron – copper alloys [82], [83]; remanences of 1.25 T and coercive forces of around 800 kA/m are achieved.

Alloy compositions and magnetic values for various Nd – Fe – B alloys are listed in Table 13. The magnetic values are for room temperature after complete magnetization. The influence of the magnetizing field strength on the magnetic values of an anisotropic magnet is shown in Figure 24 [85].

Figure 24. Effect of magnetizing field strength on the shape of the demagnetization curve for Nd – Fe – B alloys
The applied magnetic field strength in kA/m for the curves a – f is as follows:a) 400; b) 500; c) 600; d) 800; e) 1200; f) 2500

The Nd – Fe – B magnets have strongly temperature dependent magnetic properties, as is shown by the temperature coefficients for the reversible change of their J_s and H_{cJ} values (see Table 4). The strong temperature dependence of the coercive field strength means that the maximum permissible operating temperature depends on the coercive field strength at room temperature. Figure 25 shows the demagnetization curve $J(H)$ as a function of temperature for high- and low-coercive magnets [85]; the intercept of the curves with the line $B = 0$ gives the H_{cB} values. It can be seen that the 60 °C demagnetization curve of the low- coercive magnet exhibits a kink before it reaches the H_{cB} value, whereas the curve for the high- coercive magnet is linear on reaching H_{cB}, even at 100 °C. It is possible to produce Nd – Fe – B magnets with $H_{cJ} > 2000$ kA/m that have a linear demagnetization curve up to H_{cB} at 150 °C.

Table 13. Composition and magnetic values for Nd – Fe – B magnets

Production method	Isotropic or anisotropic	Composition, wt %					Magnetic values			
		Nd	Dy	Fe	B	Possible additives (0.5 – 3 %)	B_r, mT	H_{cB}, kA/m	H_{cJ}, kA/m	$(BH)_{max}$, kJ/m^3
Powder metallurgy/sintering	anisotropic	33.0		remainder	1.2		1200 – 1300	600 – 800	800 – 1000	280 – 330
	anisotropic	30.5	2.5	remainder	1.2	Al, G, V, Nb	1150 – 1200	900 – 950	1100 – 1300	260 – 280
	anisotropic	29.0	4	remainder	1.2		1050 – 1150	830 – 900	1800 – 2100	200 – 250

	isotropic	29		remainder	0.9		780 – 820	480 – 550	1100 – 1200	90 – 110
	isotropic	29		remainder	0.9		1170 – 1200	850 – 900	1000 – 1100	240 – 280

∗ Commercial product name of the powder = Magnequench.

Figure 25. Demagnetization curves of a high- and low-coercitive Nd – Fe – B magnet at varying temperature
a) 25 °C; b) 60 °C; c) 25 °C; d) 100 °C; e) 60 °C; f) 100 °C; g) 150 °C; h) 150 °C – – – high coercivity; —- low coercivity

An increase in the coercive field strength therefore increases the maximum permissible operating temperature and widens the range of applications for Nd – Fe – B magnetic materials. Despite the greater temperature dependence of their magnetic properties, as compared to Sm – Co magnets, the Nd – Fe – B magnets have $(BH)_{max}$ values superior to those of SmCo 1 : 5 and even SmCo 1 : 17 magnets over a wide temperature range (see Fig. 26).

Apart from shearing effects and thermal influences, the chemical resistance of the Nd – Fe – B alloys is important for their long-term stability. Although corrosion is negligible at room temperature and normal humidity, Nd – Fe – B magnets rapidly form rust spots at elevated temperature and humidity. The magnets can be protected by coating the surface with metals, paints, or plastics.

5. Soft Magnetic Materials

The ferromagnetic elements iron, nickel, and cobalt are the simplest representatives of the soft magnetic materials. Of these, however, only iron is industrially important in elemental form, because of its availability and low price.

The essential requirements for achieving the highest possible magnetic values in soft mag-

netic systems are maximal purity and optimal microstructure. Purity, grain size, and texture are the main factors controlling the mobility of domain boundaries and, therefore, the magnetizability of the material. In elemental systems, these are also the only quantities that can be controlled in material fabrication and treatment. Impurities and grain structure are often related in such a way that impurity particles prevent the desired formation of large grains or allow the formation of only an inadequate texture.

In the case of iron, in particular, the elements carbon, nitrogen, sulfur, and oxygen are critical for the secondary magnetic parameters (coercive force and permeability). As a result, the magnetic values of even low-carbon steels are markedly lower than those of the pure iron (Armco iron) used in soft magnetic applications, which must exhibit carbon contents well below 0.01 wt %. The content of impurities also influences the degree of cold work needed to produce optimal magnetic properties.

In order to minimize the level of impurities in the material, special attention must be directed toward the initial purity and the amounts of substances added during processing to effect deoxidation and improve the hot or cold workability; the atmospheric conditions during working and casting must also be considered. The final microstructure can be influenced by a well-defined amount of hot and cold working.

Final annealing of the finished part under suitable thermal and atmospheric conditions leads to further reductions in impurities and the formation of the optimal grain structure. The same processing steps outlined for pure iron also apply to the melt-metallurgical production of all soft magnetic materials, although they are overlain there by many other controlling variables.

The main uses for soft magnetic pure iron are in formed or massive parts for relays, electromagnet pole shoes, and shielding enclosures. Because of its low resistivity, pure iron finds only minor use as a flux-guiding stator or rotor material in electric motors and generators. With small amounts of elements such as silicon added to increase the resistivity, it is marketed as low-cost unalloyed electric sheet for applications that impose no special loss requirements.

Binary alloys based on at least one of the three ferromagnetic elements, such as Fe – Si, Fe – Ni, and Fe – Co, as well as multicomponent systems based on Ni – Fe, have long been established in industry and so can be regarded as classical soft magnetic materials. They are manufactured by melt metallurgy with subsequent mechanical working. In special cases, they can also be produced by powder methods involving molding and sintering. The second category also includes the soft ferrites, whose resistivities, orders of magnitude higher than those of metallic materials, make them suitable for high-frequency applications.

The designation "classical" is not meant to detract from the current importance of such materials; it simply indicates that they form an industrial tradition going back decades in some cases. Continuing development (chiefly in the manufacturing area) on the original basic alloys, whose compositions were selected in order to optimize specific physical properties, has brought about a steady improvement in magnetic values. The use of these materials for inductive components in electrical and electronic circuits is firmly established, and they are found everywhere in the market, in a range of application-specific variations differing in magnetic properties and core geometry.

In contrast, modern soft magnetic materials include innovative developments of recent years. First place among these belongs to amorphous materials produced by rapid solidification. Amorphous cobalt-based alloys, with their low magnetostriction, represent a further distinct improvement in magnetic values over the highest-permeability crystalline Ni – Fe-based alloys.

In the area of small transformers, for example, where operating frequencies are high, these materials make it possible to produce smaller components so as to meet user demand for the miniaturization of inductive elements. Furthermore, special new types of magnetic sensors for control applications and electronic surveillance could not be created until these materials became available.

It is not possible to foresee at present how much acceptance these materials, which are metastable, in contrast to the crystalline materials, will gain for classical applications. Their production costs are still high; their thermal stability, relatively poor; and there is some uncertainty about the long-term behavior of their magnetic values.

In addition, powder composites, which had their origins (in iron-powder cores) around the turn of the century, are described in a modern resin-bonded variant used for dynamic flux-guiding components in electric motors and for choke cores.

Table 14 lists physical and magnetic properties of soft magnetic alloys, Table 15 gives their dynamic magnetic properties, and the magnetic characteristics can be found in Table 16.

Table 16. Magnetic characterization of soft magnetic materials

Material	Characteristic features
Classical soft magnetic materials	
Pure iron	high saturation flux density, cheap material for static applications
Iron – silicon	high saturation flux density, cheap material for dynamic applications
nonoriented	isotropy of the magnetic properties
grain-oriented	anisotropy of the magnetic properties (easy axis); low losses
Iron – nickel	
E 5	strong temperature-dependance of the flux density under 100 °C
E 4	small increase in permeability at low and medium field strengths
E 3	saturation maximum in the Fe – Ni system; texture material with rectangular curve
E 2	high permeabilities at low driving fields after magnetic field annealing
E 1	very high permeabilities at low driving fields; variation of the curve shape
Iron – cobalt	saturation maximum less than for the relevant soft magnetic alloys
Soft ferrite	low eddy current losses due to very high specific electrical resistivity
Modern soft magnetic materials	
Powder-bound composite	low eddy current losses due to interparticular isolation; mechanical treatment possible
Amorphous	useful soft magnetic behavior due to lack of crystal anisotropy
Fe-based	cheap alloys with low losses
Fe – Ni-based	magnetic values between Fe- and Co-based alloys
Co-based	high magnetic values due to zero magnetostriction
Nanocrystalline	new types of Fe-based alloys with good magnetic values

5.1. Classical Soft Magnetic Materials

Classical metallic soft magnetic materials are single-phase homogeneous mixed crystals, sometimes with (orientational) superlattice structures. The addition of one or more alloying elements to a ferromagnetic base element makes it possible to control the physical properties of the system in general and, in particular, the magnetic properties. The latter are influenced by magnetic anisotropies inherent in the structure, which lead to a preferred alignment of magnetic moments in the individual domains. There are five types of anisotropy:

1) Magnetic crystal anisotropy (K_1)
2) Magnetoelastic anisotropy ($\lambda_s\sigma$)
3) Induced uniaxial anisotropy (K_u)
4) Form anisotropy
5) Exchange anisotropy

The first three are especially important for soft magnetic materials. They are described in terms of the constants K_1 (aligning effect of the crystal lattice in J/m^3), λ_s (aligning effect of tensile or compressive stress), and K_u (effect of directional ordering in J/m^3). They are influenced by imperfections in the lattice, such as foreign bodies or internal stresses.

The anisotropies have energies associated with them, and an external magnetic field H must overcome these energies in order to rotate the magnetic moment vectors away from their preferred (easy) direction. The stronger the energetic coupling to the easy direction, the more difficult it is to remagnetize a magnetic region (such as a single domain) and the higher the coercive force.

In the case of the anisotropy associated with crystal lattice structure (constant K_1), the coercive force for a favorably oriented particle is [86]

$$H_A = 2K_1 J_s$$

The magnetoelastic anisotropy describes how much the magnetization is affected by mechanical stresses; if the crystal anisotropy is neglected, then [87]

$$H_{cJ} = s\lambda_s\sigma / J_s$$

where λ_s is the saturation magnetostriction, σ is the mean internal stress, and s is a constant ($0 < s < 1.5$). The saturation magnetostriction gives the relative elastic strain $\Delta l/l$ of a polycrystalline solid in a saturating magnetic field.

Soft magnetic materials, which are characterized by low coercive forces, must accordingly have small values of both the crystal anisotropy and the product $\lambda_s\sigma$ in the direction of the driving field (working direction). This is achieved by a suitable choice of alloy composition in conjunction with final annealing of the finished part in order to establish an optimal microstructure. Depending on the magnetic level of the soft magnetic part (e.g., shielding or coil core), the annealed part may be subjected to only a limited amount of mechanical working or loading, or to none; otherwise, plastic deformation may result

in new magnetic hardening. Dislocations generated in this way, like impurity particles, precipitates, and grain boundaries, lead to undesirable interactions with the domain boundaries.

Because the classical soft magnetic materials are all polycrystalline, minimizing the anisotropy effects in the working direction always involves either finding compromises or creating the most isotropic structure possible.

The crystal anisotropy can be used to control the shape of the hysteresis curve. If, for example, recrystallization annealing is used to produce a distinct texture in the strip direction in a cold-worked strip material, then the hysteresis loop measured in this direction will be extremely rectangular ($B_r/B_s \lesssim 1$).

Induced uniaxial anisotropy, which can be generated by tempering in a magnetic field, involves one-dimensional orientational superlattice structures of like atoms. This kind of anisotropy can also be used to control the shape of the hysteresis curve.

Magnetic anisotropies thus provide an important way of manipulating the secondary magnetic parameters of soft magnetic materials. But the effectiveness of these measures depends on the fabricated part having a geometry adapted to the driving field direction; this requirement leads to standardized core shapes.

5.1.1. Iron – Silicon Materials

Electrical power technology uses generators, motors, chokes, transducers, and transformers to produce, transform, and distribute electrical energy. The windings carry relatively large electrical currents at a constant voltage in the industrial frequency range (usually 50 or 60 Hz line frequency), and magnetic fields or magnetic fluxes result from these currents. Guiding the a.c. magnetic fluxes as efficiently as possible means using easily magnetizable, low-loss soft magnetic materials with high usable flux densities. This application requires large amounts of material, so that the first criterion for material selection is low cost. The term electric sheet covers all the iron-based core materials used in this field.

The technically and economically effective dynamic use of soft magnetic materials in electrical machinery and transformers requires low magnetic losses and high efficiencies. Pure iron satisfies these requirements to only a limited degree because of its low resistivity, and so it has been necessary to find low-cost alternatives.

The magnetic loss P_{Fe} of a magnetic material is the sum of hysteresis losses P_H (the area enclosed by the static hysteresis loop) and eddy-current losses P_E:

$$P_{Fe} = P_H + P_E$$

According to classical eddy-current theory, derived from Maxwell's equations and neglecting the domain structure, the eddy-current losses P_E (in W/kg) for a sinusoidal flux uniformly distributed in a sheet with density d is

$$P_E = \frac{\left(\pi D \hat{B}\right)^2}{6\varrho d} \cdot f^2$$

Small sheet thicknesses D and high resistivities ϱ are therefore necessary to reduce eddy-current losses.

Figure 27. Effect of silicon in iron on the transition temperature γ-α (A); on the electrical resistivity (B); on the crystal anisotropy (C); and on the saturation polarization (D) [91]

The addition of silicon to iron gives a marked increase in resistivity (see Fig. 27), but at the cost of the saturation flux density. Since silicon forms a homogeneous solution in iron up

to a few wt % (see Fig. 28), no magnetic hardening occurs. Furthermore, silicon has the advantage of reducing crystal anisotropy. As the silicon content increases, however, the alloy loses workability, especially at room temperature, so that high-silicon electric sheet can be fabricated only by hot rolling. The commercial use of over 4.5 wt % Si is thus no longer attractive.

Figure 28. Iron-rich side of the Fe – Si phase diagram [92]

Siliconized electric sheet is available in thicknesses down to 0.05 mm. Such extremely thin sheets, however, are reserved for higher-frequency applications, where they are used in tape-wound toroidal or C (cut) cores for repeater coils, chokes, and other devices. A secondary use is in stampings for the power area, which involves sheets of standardized thicknesses down to 0.23 mm. Standard series of material qualities are differentiated by sheet thickness and loss values [88], [89].

Iron – silicon electric sheet materials are classified in two groups according to the crystallographic orientation of the strip material in the final annealed condition:

1) Non-oriented (NO) material
2) Grain-oriented (GO) material

Because of their isotropic magnetic values in the sheet plane, NO materials find use chiefly in rotating electrical machinery, while the anisotropic GO materials are employed for cores in power and distribution transformers [90]. Cores made of laminated sheets with insulation between layers come in the usual geometries.

Important gains in magnetic properties have been achieved for both classical electric-sheet groups, not least because of potential competition from novel amorphous iron-based alloys starting in the 1970s and, later, from high-silicon nanocrystalline alloys produced by rapid solidification.

5.1.1.1. Non-Oriented Electric Sheet

The fabrication of electric sheet from ordinary steel began in the late 1800s with the advent of electrification. Silicon was first used as an alloying element at the beginning of the 1900s. Only hot-rolled low-silicon sheet with a relatively high carbon content was available at first.

However, because hot rolling is a costly process for strip production, and because such strip is not as high in quality (purity, dimensional stability, surface finish) as cold-rolled strip, attempts to make cold-rolled electric sheet began soon afterwards. Today, electric sheet containing up to 3.5 wt % Si is generally made by cold rolling [90].

The addition of 0.3 – 0.6 % Al further reduces the magnetic loss [93], [94] by enhancing the resistivity, diminishing the crystal anisotropy, in-

creasing the grain size, and producing a beneficial change in the structure and size of inclusions [95]. Commercial NO electric sheet available today is generally an Fe – Si – Al alloy. Its production involves the following steps:

1) Melting the alloy by special methods to increase the purity [96]
2) Casting into ingots
3) Hot rolling to intermediate thicknesses of 1.8 – 2.5 mm
4) Pickling
5) Cold rolling to final thicknesses of 0.35 – 0.65 mm
6) Final annealing in two stages: a) decarburizing annealing in a humid atmosphere between 800 and 900 °C and b) coarse-grain recrystallization annealing above 1000 °C

Figure 29. Effect of the average grain diameter on the magnetic loss [98]
a) Magnetic loss $P = P_H + P_E + P_A$; b) Hysteresis loss P_H; c) Abnormal loss P_A; d) Classical eddy current loss P_E (0.41 – 0.60 W/kg depending on the alloy grade)

Good NO electric-sheet qualities with low losses at high flux densities ($\hat{B}$ = 1.0 and 1.5 T) must meet stringent requirements for texture, grain size, purity and surface finish of the strip, along with the secondary condition that the silicon content be as high as possible. In particular this means [97], [98]:

Figure 30. Magnetic loss as a function of sheet thickness for two surface states
a) Dry annealing; b) Two-stage (wet + dry) annealing

1) Establishment of a magnetically isotropic recrystallization texture in the strip plane– the cube-face texture (100) [0kl], also called a "wagonwheel" texture.
2) Recrystallization annealing (see Fig. 29) to produce a grain size (0.10 – 0.15 mm) optimal for the later service conditions. This step results in either optimization of the loss for a given flux density or optimization of the permeability.
3) Attainment of high purity, in particular with extremely low sulfur, oxygen, nitrogen, and carbon contents (in the ppm range). In this way, the formation of coarse grains and texture is improved, and hysteresis losses are reduced.
4) Prevention of surface oxidation and the resulting formation of fine grains at the surface. This is accomplished by optimizing the annealing atmosphere and eliminating

decarburizing annealing through the use of extremely low-carbon alloying techniques. Figure 30 shows how the magnetic loss $P_{1.5}$ depends on the sheet thickness for two surface conditions.

Commercially available NO electric-sheet qualities in thicknesses of 0.5 and 0.35 mm exhibit 50 Hz losses $P_{1.5}$ of between 2 and 4 W/kg (2 W/kg for the 0.5 mm sheet is the peak value).

5.1.1.2. Grain-Oriented Electric Sheet

Substantial improvements in the magnetic quality of electric sheet, in the sense of lower losses and higher permeabilities, are possible with the anisotropic GO materials. In principle, the requirements of high purity and low internal stress are the same as for the NO materials, but there is the constraint that lattice imperfections must be introduced in order to control texture formation and domain configuration.

Figure 31. Textures of soft magnetic materials
A) Cube texture; B) Goss texture

Specially matched cold-rolling and annealing practices combined with the addition of "inhibitors" in melting produce a texture such that the grains have the [100] easy magnetization direction of the body- centered cubic mixed FeSi crystal preferentially oriented in the rolling direction. In the (100) [100] cube texture, the longitudinal and transverse directions of the strip are magnetically equivalent. A (110) [100] texture is called a " Goss texture" after N. P. Goss, who developed the process in the United States in 1934 [99]. All commercial GO electric sheet produced today has this orientation (see Fig. 31).

Figure 32 illustrates the history of high-quality GO electric sheet in a time plot of magnetic loss $P_{1.7}$ for RGO (regular grain-oriented) and HGO (high-permeability grain-oriented) qualities. The advantages of the HGO material [100], which appeared in the 1970s, result from improved sharpness of orientation and grain-size control with the simultaneous imposition of a mechanical tensile stress in the sheet surface by the insulation (stress coating). The magnetic loss can be further reduced by decreasing the strip thickness–provided that a good Goss texture is preserved (which becomes harder to do as the strip becomes thinner) [101–103] and the strip surface is kept smooth–in conjunction with domain size reduction by laser scribing (LS) or mechanical or chemical methods.

Figure 32. History of high-quality GO electric sheet in terms of the magnetic loss $P_{1.7}$ [98]
○ RGO, $d = 0.30$ mm; ● HGO, $d = 0.30$ mm; ■ HGO (LS), $d = 0.23$ mm; △ HGO (LS), $d = 0.20$ mm

Markedly lower losses $P_{1.7}$ of 0.21 W/kg at 50 Hz were measured on 0.031 mm thick laboratory fabricated sheets after tertiary recrystallization and domain size reduction by chemical etching [104]. Today, strip 0.23 mm thick is by far the most commonly used for commercial applications at line frequencies (50 Hz in Europe, 60 Hz in the United States) [105], where the lowest possible losses must be achieved along with safe mechanical handling.

Improvements in the process for making thinner strips (0.2 mm and less) are also being strongly advised in Europe [106]. By way of example, Figure 33 illustrates how magnetic loss depends on strip thickness in grain-oriented electric sheet. In contrast to the NO materials discussed in Section 5.1.1.1, as shown in Figure 32, the measured losses are distinctly lower despite the higher measuring flux density. Since 1970, as other sources [107] confirm, losses have been cut by an average of 50 % in GO electric sheet, and this development is clearly reflected in energy costs. According to [108], a 10 % reduction in magnetic losses yields an energy cost saving of € 36×10^6 in the Federal Republic of Germany alone.

Figure 33. Magnetic loss as a function of sheet thickness in grain-oriented electric sheet [106]

The production of high-quality GO electric-sheet materials is complicated, and it is necessary to monitor a large number of process parameters that control the microstructure and bear crucially on the magnetic properties of the sheet in the final condition. A vitally important step is secondary recrystallization to generate the Goss texture, which should have the sharpest possible orientation. The mechanisms by which grain growth, texture, and control by particles of a second precipitated phase (such as manganese sulfide or copper sulfide, the "grain growth inhibitors") interact have been quantified only quite recently; according to [109], undisturbed secondary recrystallization with selective grain growth is possible only if certain preconditions–described in terms of an "effective grain radius" and an "inhibitor factor"–have been established in the primary structure. These quantities express the driving and inhibiting forces for optimal secondary recrystallization.

The strip surface should be as clean and smooth as possible; combined with the morphology of the electrical insulation on the strip, the surface finish represents an important factor determining the magnetic loss. The insulation layer is produced during the three-step final heat treatment of the cold-rolled strip. Table 17 lists the processes that take place in the several steps.

Domain size-reduction operations serve to cut losses by diminishing the anomalous eddy-current losses $P_A = P_W - P_E$ (excess losses), which result from the dynamics of the domain boundaries and cannot be derived directly from classical eddy- current theory. Excess losses result from the wide spacing of domain walls in very coarse structures (grain diameter 1 – 20 mm), which lead to movement of the domain walls over long paths upon remagnetization. Because no consistent theory of losses has yet been devised, the following simple treatment by Pry and Bean [110] is used to quantify this phenomenon.

If the spacing between domain walls is L and the sheet thickness is D, then for the case $2L > 0$ an anomaly factor

$$\eta = 1.63 \cdot 2L/D$$

is used to correct the classical eddy- current losses such that

$$P_{Fe} = P_H + \eta P_E$$

A domain structure with close wall spacing accordingly leads to lower total eddy-current losses, $P_W = \eta P_E$. If $L \ll D$, $\eta \to 1$, and the anomalous losses become negligible.

This analysis is being extended on the basis of statistical theories of loss [111–113]. Such theories also attempt to describe the situation in the NO materials, which is more difficult because the complicated microstructure implies more complex domain structures.

If a core (laminated or tape-wound toroidal) is made from strip already treated for domain size reduction, then for the treatment to remain effective in the final condition it must be stable against annealing, since mechanical working of electric sheet must generally be followed by a further stress-relief annealing step.

Table 17. Heat treatment in production of GO electric sheet

Heat treatment step	Conditions	Effect on	
		Fe – Si matrix	Insulation coating
1	fast continuous strip annealing at ca. 850 °C under moist H_2/N_2 atmosphere	decarburization	formation of fayalite (Fe_2SiO_4) and silicon dioxide (SiO_2) base layer
2	coarse-grain annealing in tight coil below 1200 °C for several days	recrystallization	reaction with MgO used as adhesive protection, yielding forsterite (Mg_2SiO_4) glass film
3	final annealing at 850 °C	stress relief	application and firing-in of a phosphate coating

Targets for development at present are a magnetic loss of $P_{1.7} = 0.4$ W/kg and economically produced strip 0.18 mm thick. Substantial increases in Si content (up to 6.5 %) through new strip-casting processes, in combination with smaller strip thicknesses, are promising trends in classical electric-sheet materials [106].

Figure 34. Iron – nickel phase diagram

5.1.2. Nickel – Iron Materials

The classical soft magnetic Ni – Fe materials cover a wide range of nickel contents, from 30 to 85 wt %; some contain small amounts of other substances. Figure 34 shows the phase diagram of the binary system Fe – Ni; Figure 35 presents curves of saturation magnetization and Curie temperature for this system. On the iron-rich side, the lattice is body-centered cubic below the Curie temperature; the industrially important nickel-rich alloys, on the other hand, crystallize in a face-centered cubic lattice. In the vicinity of Ni_3Fe, there is also an isotropic superlattice structure formed below 500 °C; this consists of short-range or long-range ordering and can be influenced by special cooling or tempering treatments. The superlattice structure is particularly important for the magnetic properties of alloys lying in this region.

Figure 35. Absolute saturation $4\pi I_0$, saturation magnetization $4\pi I$ at 20 °C, and Curie temperature T_c in the Fe – Ni system [114]

The various crystallographic structures of the iron- and nickel-rich alloys result in a variety of easy directions for magnetization, because of the sign alternation of the crystal anisotropy constant K_1. Figure 36 shows how K_1 behaves in the Fe – Ni system.

When $K_1 \gg 0$, that is, on the iron-rich end, <100> is the easy direction. Above 36 % Ni, K_1 is small and positive; at ca. 75 % Ni, after rapid cooling from temperatures above 500 °C, it passes through zero; thereafter it falls to more negative values. In this region, the cube diag-

onals <111> of the face-centered cubic lattice are magnetically easy.

Figure 36. The crystal anisotropy constant K_1 in the Fe – Ni system [117]
a) Quenched; b) Oven cooled (ca. 50 K/h); c) Slowly cooled (ca. 2.5 K/h)

Figure 37. Magnetostriction constants λ_{100}, λ_{111}, and λ_s for the Fe – Ni system [118]

By altering the cooling conditions and the associated ordering, it is possible to shift the zero of K_1 toward lower Ni contents. In conjunction with further additions of Mo, Cu and Cr, this effect is particularly important for a markedly high level of the soft magnetic values in high-nickel materials (see Section 5.1.2.1).

The magnetostriction constants λ_{100}, λ_{111} and λ_s in the Ni – Fe system start out positive and pass through zero above 80 % Ni. Ordering processes do not play an important role here, however, as can be seen in the slight differences between the values after fast and slow cooling. Furthermore, λ_{100} crosses through zero at about 45 % Ni, while λ_s, the saturation magnetostriction in the field direction for polycrystalline structures, has a zero corresponding nearly to pure iron (see Fig. 37).

These points show which alloy compositions in the Ni – Fe system promise good soft magnetic values and how it may be possible to optimize the values by the addition of other elements. Because the smallest possible (or even vanishing) magnetostriction and/or crystal anisotropy are requisites for high permeabilities, while high saturation flux densities and high resistivities are desirable, essentially three alloy regions are of interest:

1) High-nickel alloys (> 70 % Ni)
2) Alloys with moderate nickel contents (45 – 65 %)
3) Low-nickel alloys (ca. 36 % Ni)

These alloys are prepared by melting at atmospheric pressure or under vacuum. Vacuum degassing is indispensable if maximum purity is to be achieved; small amounts of Al, Mg, or Si are added for deoxidation. The addition of Mn fixes the sulfur and thus improves the workability. Another possibility is to use the powder-metallurgical techniques of pressing and sintering, which can produce high-purity, highly homogeneous materials.

Whether produced by melting or sintering, the blocks are next thinned to a few millimeters by hot rolling, then cold-rolled, with well-defined intermediate annealing in the range 800 – 1000 °C, to thicknesses of 0.003 – 1 mm, depending on the desired final thickness. Surface treatments such as planing, pickling, and milling are needed especially after the hot-working operations.

Sheet rolled to the final thickness is made into tape-wound cores with insulation between layers, laminated cores, or special forms. Special heat treatment is required to produce the optimal magnetic properties for the particular composition. Initially there is a high-temperature final anneal above 1000 °C under a reducing atmosphere. In the course of this operation, the structure is purified by the removal of C, N,

S, and O, and grain growth takes place by secondary recrystallization. Thus an essential condition for good soft magnetic behavior is satisfied: the elimination of internal imperfections that hinder domain-boundary movement.

Figure 38. Initial permeability of important soft magnetic alloys as a function of the year of discovery [122]

Figure 39. Favorable alloy compositions with Supermalloy behavior (B, D, E, H, K) in the Ni – Cu – (Fe + Mo) system [121]

This anneal is followed by tempering under conditions that depend on the alloy composition. This operation is carried out in the ordering region or in a magnetic field below the Curie temperature. Comprehensive accounts of soft magnetic iron – nickel alloys appear in [114–116].

5.1.2.1. High-Nickel Alloys

The development of high-nickel Fe – Ni alloys, also called Permalloys, began in the 1920s when the binary Permalloy (75 wt % Ni) was discovered by Elmen [119]. Later advances were mu-metal (76 % Ni, 5 % Cu, 2 % Cr), M 1040 (72 % Ni, 14 % Cu, 3 % Mo), and Supermalloy (79 % Ni, 5 % Mo, and others) [120]. Figure 38 shows the progressive improvement of the initial permeabilities in these alloys versus the year of discovery. For the sake of comparison, the earlier state of the art–soft magnetic iron and iron – silicon materials–is also shown; Permalloy represents a substantial gain over these. In Supermalloy, the composition for the maximum magnetic values is still restricted to a very narrow range. By varying the nickel content and adding copper and molybdenum, Assmus and Pfeiffer [121] showed that peak magnetic values are not limited to a certain composition but occur over a broader series of alloys. The copper-free Supermalloy thus stands at the beginning of an alloy series that extends to the ternary system Ni – Cu – (Fe + Mo) (see Fig. 39).

Replacing part of the Fe with Mo moves the zero point of K_1 from 75 % Ni in binary Permalloy (Fig. 36) toward higher nickel contents, while adding copper shifts the zero of λ_s (about 80 – 81 % Ni in Figure 37) toward lower nickel contents without affecting K_1. In comparison with current Permalloy materials, however, the maximum initial permeability of ca. 100 000 for the original Supermalloy appears relatively low.

The clear improvement now attained in the magnetic values of high-nickel alloys (μ_4 values $> 250\,000$; see Table 15) is due to optimized chemical compositions, based on the findings cited above, and the development of heat-treatment programmes specially tailored to them. In this way, the detrimental effects of crystal anisotropy and magnetostriction are further reduced. The alloy containing 77 % Ni, 5 % Cu, 4 % Mo, and 14 % Fe is an example of the high-nickel materials common today (77 % Ni Permalloy).

Furthermore, advances in technique and improvements in melting, processing, and annealing have led to continuing and significant reductions of internal perturbations in industrial-scale melt metallurgy. Impurities such as oxygen, sulfur, and carbon have a very harmful effect on soft magnetic behavior and must be eliminated as far as possible in the final high-temperature reducing anneal.

Figure 40. Static and dynamic hysteresis curves of a rich nickel alloy
A) Optimally tempered: H_c (static) = 0.4 A/m, B_r (static) = 0.52 T, μ_4 (dynamic) = 342 000, μ_{max} (dynamic) = 455 000; B) Magnetically tempered: H_c (static) = 0.7 A/m, B_r (static) = 0.20 T, μ_4 (dynamic) = 78 000, μ_{max} (dynamic) = 110 000
a) Static; b) Dynamic (50 Hz)

Heat treatments in very narrow temperature ranges below 550 °C, or under well-defined cooling conditions, are essential for establishing the charge-specific magnetically optimal tempering condition in order to realize the necessary critical degree of close-range order. In this way, departures from the optimal alloy composition can be subsequently corrected. Figure 40 shows the static and dynamic (50 Hz, sinusoidal flux density) hysteresis curves for an optimally treated alloy from this group, measured with a tape-wound toroidal core having a strip thickness of 0.1 mm.

In addition, the selection of tempering temperature makes it possible to control the temperature dependence of the permeability at typical service temperatures. In this way, either maximum permeability at room temperature or nearly constant permeability between − 25 and + 80 °C (temperature compensation) can be achieved. Figure 41 gives a plot of the permeability μ_7 versus temperature for the tape-wound toroidal core of Fig. 40 A and also for a temperature-compensated material.

Figure 41. Permeability μ_7 of an optimally tempered (a) and temperature compensated (b) toroidal tape-wound core (made from a high-nickel alloy) as a function of temperature

Another possibility for controlling the shape of the hysteresis loop is tempering in a magnetic field below the Curie temperature, which leads to magnetically-induced anisotropic close-range ordering (directional ordering of Fe – Ni pairs). Figure 40 B shows a flat hysteresis loop realized in this way.

The microscopic causes of these effects lie in energetic stabilization of certain domain structures, which lead to round or rectangular hysteresis loops depending on the direction of the driving field. Practical application of these processes, however, presupposes certain core geometries such as the tape-wound toroid.

The very high magnetic values in industrial Permalloys, coupled with low coercive force, low magnetic loss, and high permeabilities at low driving field strengths, are important chiefly in inductive components subject to the most

stringent requirements. High-quality soft magnetic materials permit small core dimensions, so that the demand for miniaturized components can be satisfied.

5.1.2.2. Medium-Nickel Alloys

The group of nickel – iron alloys with moderate nickel contents (45 – 65 % Ni) exhibits the highest saturation flux densities of all the industrially important Fe – Ni alloys. The magnetic values are not as high as those of the modern Permalloy materials, but peak values are up to the lower limit of the high-nickel materials. Because the saturation flux densities are nearly twice as great, the hysteresis curve displays high $\hat{B}$ values or wide induction changes ΔB. This material group is thus also attractive for special applications in power transmission, primarily when very low losses are required.

Alloys with over 53 % nickel have only a weakly positive crystal anisotropy, so that they attain markedly higher magnetic values than do the lower-nickel materials. At high nickel contents (65 %) with optimized tempering below 550 °C, K_1 can even vanish. Furthermore, it is possible to carry out tempering in a magnetic field so as to bring about a large K_u value, since the high Curie temperature and the high saturation flux density create favorable conditions for magnetic-field-induced diffusion processes. In this way, as in the high-nickel alloys, the hysteresis loop can be varied from flat to rectangular (magnetic-field-induced rectangular loop). The addition of about 2 % Mo increases the resistivity and thus improves the dynamic behavior. In alloys with lower nickel contents (below 60 %), the effect of crystal anisotropy can be greatly reduced through mutual compensation of K_1 and K_u; this gain is also reflected in high magnetic values.

At nickel contents below 53 %, the stronger influence of crystal anisotropy ($K_1 > 0$, easy direction <100>) clearly lowers the level of magnetic values. In these alloys, however, it is possible to generate a cube texture in the strip plane through cold working (> 95 %) and coarsening of the primary recrystallized structure by annealing between 1000 and 1100 °C. As a result, with magnetization in the rolling direction and perpendicular to it, an extremely rectangular hysteresis loop is obtained; this behavior is especially favorable for the magnetization conditions in core laminations.

Annealing above 1100 °C leads to a large increase in grain size through secondary recrystallization and disrupts the cube texture if any secondary texture was still present. The initial permeability does increase, but the hysteresis loop loses its rectangular shape.

Typical magnetic values are listed in Table 15.

5.1.2.3. Low-Nickel Alloys

At the iron-rich end of the binary Fe – Ni system the group of alloys with about 36 % nickel forms the end of the series of industrially important high-permeability soft magnetic alloys. Alloys containing 30 % Ni are assigned to a separate group because of their strongly temperature-dependent magnetic properties, among which the saturation flux density is particularly important (see Section 5.1.5).

In comparison with the 45 – 49 % nickel materials, this group has lower permeabilities and higher coercive forces. The values are similar to those of siliconized electric sheet, but here the resistivities are far higher and the cold-working properties are significantly better. By virtue of the last point, thin strip can be produced and then worked further by deep drawing. The 36 % NiFe materials thus form, so to speak, a bridge between cheap electric sheet, with the mechanical constraints on its use, and more costly high-quality Ni – Fe alloys with more than 45 % nickel.

The saturation flux density of 1.3 T for the 36 % NiFe alloys is still relatively high. In combination with the high resistivity, this feature makes the material suitable for power applications in the medium-frequency range. If the nickel content is further reduced, the saturation drops sharply. Like the medium-nickel alloys, the 36 % Ni alloys are manufactured with the smallest possible amount of additives so as not to lower the saturation value further.

Special manufacturing processes make it possible to control the relationship between permeability and field strength, making the curve flatter or steeper (see Fig. 42).

Figure 42. Steep and flat permeability curves of a 36 NiFe alloy

5.1.3. Iron – Cobalt Alloys

A ternary Fe – Co – V alloy (Permendur) represents the only material from this alloy group that is of any industrial value today. Binary Fe – Co alloys containing 27 and 35 % cobalt are of only marginal importance (special high-temperature applications). Figure 43 shows the phase diagram of the Fe – Co system, which can also be used in characterizing phase transitions in the Fe – Co – V system.

The alloy Fe49Co2V is characterized by a high saturation flux density of 2.35 T, which represents the largest value of all the soft magnetic alloys. This value is attained, however, only at relatively high driving field strengths, roughly 10 kA/m. Furthermore, the Curie temperature is high (T_C= 950 °C), and large maximum permeabilities can be found at high temperatures. The room-temperature magnetic values are only moderate. The iron – cobalt alloys are expensive because of their high cobalt content and are used chiefly for inductive elements in aerospace applications, where size and weight savings are important.

The mechanical working of iron – cobalt alloys causes some problems. In a purely binary 50 FeCo system, cold working would be impossible because of the very rapid superlattice structure formation in the α-phase, the resulting embrittlement of the material, and the tendency for intergranular cracking.

Figure 43. Iron – cobalt phase diagram [123]

The addition of vanadium slows down the ordering processes commencing below 750 °C, so that a disordered α state, generated by annealing just below the $\alpha - \gamma$ phase-transition boundary, can be quenched at room temperature. This creates better conditions for cold working by setting up a ductile mixed structure consisting of the α-phase and martensite and containing no superlattice structure.

For magnetic optimization, it is useful to reintroduce some degree of ordering in the final heat treatment (after the conclusion of mechanical working) in order to control the zero crossing point of K_1.

Experimental results [124] indicate that the addition of 0.2 % niobium or tantalum in place of the 2 % vanadium gives the same gain in ductility and further improves the magnetic values (B_s= 2.45 T).

5.1.4. Soft Ferrites

Ferritic materials have been known for over 50 years and have been in large-scale industrial use

Figure 44. Flow-sheet for the production of soft magnetic ferrites

since the end of the 1940s. Among soft magnetic ferrites, the following classes are distinguished on the basis of the underlying crystal structure:

1) Cubic ferrites with spinel structure
2) Hexagonal ferrites with magnetoplumbite structure
3) Hexagonal ferrites of higher order
4) Ferrites with garnet structure
5) Orthoferrites

All these groups have found widespread application in industry [125].

Cubic ferrites have the chemical formula $MO \cdot Fe_2O_3$, where M is a divalent metal ion such as Fe, Ni, Co, Mn, Mg, Cu, Ti, Cd, or Zn, or a combination of such ions. They crystallize in the spinel structure, in which the oxygen ions form a face-centered cubic (fcc) lattice. The metal ions occupy the remaining tetrahedral (8 per unit cell) and octahedral (16 per unit cell) sites.

Other cubic soft ferrites of industrial importance, in addition to the nickel type, are the mixed ferrites, in which zinc figures as a sec-

ond metal ion. The MnZn and NiZn ferrites are the most common materials in this category:

Ni ferrites: $(Ni, Fe)O \cdot Fe_2O_3$
Ni – Zn ferrites: $(Ni, Zn, Fe)O \cdot Fe_2O_3$
Mn – Zn ferrites: $(Mn, Zn, Fe)O \cdot Fe_2O_3$

Hexagonal soft ferrites represent a mixture of cubic spinel ferrites and hexagonal barium ferrites with the magnetoplumbite structure (see Section 4.1.4).

Because of their ceramic nature, ferrites exhibit much higher room-temperature resistivities than metallic materials (see Table 14). They are thus especially suitable as cores in inductive components for super-high-frequency dynamic service. Cubic ferrites can be operated into the MHz range, and hexagonal ones into the GHz range, without any drastic loss of magnetic properties due to eddy- current losses. In comparison with metallic soft magnetic materials, however, the much lower saturation flux density (a result of the structure) must be considered a drawback. The brittleness of ferritic materials also restricts the possibilities of machining such magnets.

Figure 45. Shapes of soft ferrite cores [150]
A) E cores; B) U cores; C) Pot cores; D) Cross cores; E) RM cores; F) TT cores

Soft magnetic ferrites are produced by molding and sintering. As is common with soft magnetic materials, the starting materials must be as pure as possible. The magnetic properties are governed equally by the chemical reaction yielding the oxides and by the kinetics of sintering. The degree of oxidation, oxygen content, and grain size are among the important parameters that must be precisely controlled but which also offer possibilities for variation. In order to avoid lowering the saturation flux density, the residual porosity after sintering should be made as small as possible. Figure 44 shows a flowsheet for the production of soft magnetic ferrites [126]. A number of largely standard core shapes (e.g., U, E, EC, ETD, and RM cores; see Fig. 45) and matching accessories such as bobbins are available for applications in electronics.

The coercive forces of soft magnetic ferrites range from 10 to 1000 A/m; the maximum saturation flux density is ca. 0.5 T. Initial permeabilities of up to 40 000 can be realized with Mn – Zn ferrites, but only at operating frequencies of a few kHz and in extremely narrow ranges of working temperature (see Fig. 46). Nickel and Ni – Zn ferrites offer initial permeabilities of about 1000, but these figures hold well into the MHz range.

Figure 46. Permeability as a function of temperature for high permeable ferrites [127]

It must be acknowledged that only a portion of the magnetic properties can be optimized in any one ferritic material. Maximum initial permeabilities and low losses cannot be combined in one material, so that there is always an application-specific compromise. Typical compositions for high initial permeabilities (zero crossing of the crystal anisotropy) are close to 26 mol% MnO, 52.5 mol% Fe_2O_3, balance Zn; while high saturations and Curie temperatures for power applications can be attained at 35 mol% MnO, 54 mol% Fe_2O_3, balance Zn.

While ferrites were formerly used chiefly as RFI suppression choke core materials, more recently they have attracted interest in wide-band repeating coils and power applications (switched mode power supplies). Table 18 shows the relevant magnetic properties for various applications. The increasing demand for wide-band

Table 18. Relevant magnetic properties of soft magnetic ferrites for various applications

Application	Magnetic property*										
	a/μ_i	D/μ_i	$\tan/\mu_i$	μ_i	R_P	P_V	μ_a	T_c	$\Delta L/L_o$	η_B	A_L
Filters	x	x	x								
Wide-band repeater coils				x	x						
Repeater coils, chokes (Power applications)						x	x	x	x		
Inductance coils									x	x	x

* a/μ_i: temperature coefficient; D/μ_i: disacomodation factor; $\tan/\mu_i$: loss factor; μ_i: initial permeability; R_P: parallel loss resistance; P_V: power loss; μ_a: amplitude permeability; T_c: Curie temperature; $\Delta L/L_0$: inductivity rise; η_B: hysteresis correction value; A_L: inductivity factor

repeating coils results from new digital transmission techniques in communications (e.g., ISDN), where ferrites compete with metallic wound strip cores, often amorphous in nature, which offer higher permeabilities.

5.1.5. Special Soft Magnetic Materials

Materials whose magnetic polarization is strongly temperature-dependent under service conditions of −30 to 120 °C are used chiefly to compensate the temperature dependences of permanent-magnet systems. Such temperature-compensating alloys must satisfy the following requirements:

1) well-defined slope of polarization curve in service temperature range
2) exact fixing of Curie temperature above room temperature or of its apparent equivalent at a certain working field strength below saturation
3) reversible variation of magnetic properties on heating and cooling

Industrially important for this application area are Fe–Ni–C alloys with closely controlled nickel contents between 29 and 31 wt %. Variations of as little as 0.1 % in the nickel content or 0.01 % in the carbon content lead to changes of 10–20 mT in polarization at 20 °C. The addition of carbon up to about 0.3 wt % affords thermal stabilization of the ferromagnetic γ-phase. Other materials with similar thermomagnetic properties, but having lower slopes of the polarization versus temperature curve, are 30NiFe alloys with added chromium, and Ni40Cu.

The material is delivered as cold-rolled strip or stampings made from such strip, already heat-treated, and with a definite temperature dependence of polarization. Figure 47 shows three typical curves that can be produced by varying the nickel content slightly.

Figure 47. Polarization as a function of temperature for three temperature-compensation Fe–Ni–C alloys

Important applications are in magnetic shunts for the permanent-magnet flux in magnetic circuits of tachometers and measuring instruments, in thermomagnetic switches, in control components, and as temperature-dependent inductances.

If stringent requirements are imposed on the thermal or corrosion resistance of soft magnetic materials, soft magnetic chrome steels are candidates for use. These are ferritic stainless steels containing 14–24 wt % chromium and less than 0.08 wt % carbon. In comparison with the non-oriented electric sheet used under nor-

Figure 48. Production process for powder- composite magnetic materials

mal conditions, here the level of magnetic values is markedly lower while losses are higher and saturation flux densities and permeabilities are lower.

5.2. Modern Soft Magnetic Materials

5.2.1. Powder Composite Materials

Modern soft magnetic powder composites are a direct development of the classical powder core. The idea of a composite made up of particles electrically isolated from one another goes back to HEAVISIDE [128]. Iron powder cores were developed as early as 1932 by VOGT [129].

The production of soft magnetic sintered components starts with metal powders, which may consist of the elemental metal (Fe), a mixture of several elemental powders (Fe, Si, Ni, Co), or alloy powders (Fe – P, Fe – Si, Ni – Fe, Co – Fe, Ni – Fe – Mo). These powders are molded, then subjected to thermal compaction. Such powder composites are multicomponent structures. In addition to the basic magnetic powder, electrically insulating additives and organic or inorganic binders are included. In a preparatory step, the metal powder grains are surrounded as completely as possible by electrically insulating skins. The mixture is then converted to a compact under high pressure. Parts can also be fabricated by injection molding (see Fig. 48). Since these parts cannot be subsequently compacted by sintering, a binder must provide the mechanical stability of the formed part. Depending on the nonmetallic components used and their thermal stabilities, heat treatment serves to relieve mechanical stresses and harden the composite. The final density must accordingly be attained directly through the compaction process.

Modern powder composites are made with organic insulating and binding agents. Such resin composites can then be shaped by mechanical methods such as turning, milling, drilling and boring, so that large sizes and complicated geometries not directly obtainable by molding can still be realized. In contrast to laminated core shapes, a powder composite is isotropic in its magnetic properties.

From the magnetic standpoint, a powder composite represents a circuit strongly sheared by the air gaps inherent in the material. The permeability level in a static measurement is therefore very low. Iron-based powder composites offer a maximum initial permeability of 100. Because the magnetic particles are electrically isolated from one another, the electrical volume resistance is high; at the same time, however, eddy-current losses are drastically reduced, so that the permeability remains approximately

constant under dynamic driving up to the MHz range.

The strong shearing also leads to very good d.c. preloadability. Because the metallic base materials have higher saturation flux densities, this represents a clear advantage over ferrites. Given an appropriate choice of mean grain size and grain-size distribution of the magnetic particles in the range between 10 and 100 µm, hysteresis losses–which are the dominant loss component over a wide range of frequencies– can be minimized. If the grains are too large, the eddy-current losses increase to an undesirable degree; if they are too small, the background hysteresis loss becomes too great. The shape of the magnetization curve and the maximum saturation flux density can be adjusted through the metallic filling factor of the composite and the type of powder used (Fe, Fe – Si, Fe – Ni).

Figure 49 shows the static magnetization curves for three iron-based powder components having different filling factors, with the curve for a soft magnetic sintered iron for comparison.

Figure 49. *B* (*H*) curves for three iron-based powder components of varying density (a) and a sintered iron material (b)

Given optimal isolation of the particles, the magnetic properties of soft magnetic powder composites can be improved only by reducing the hysteresis losses. Since the required annealing temperature is high, mechanical stress relief in the molded part is possible only with inorganic insulation. It is certainly advantageous to use amorphous metal powders with vanishingly low magnetostriction. At present, however, there is no low-cost compaction process for such future products.

5.2.2. Rapidly Quenched Materials

The magnetic materials dealt with in the previous chapters all exhibit a crystalline lattice structure. Associated with this is an inherent magnetocrystalline anisotropy, which must be minimized if optimal soft magnetic properties are to be obtained. In addition, all industrially used alloys have a polycrystalline grain structure, which must either be made as coarse grained as possible by secondary crystallization, or whose texture must be adapted to the shape of the intended magnetic core.

By means of rapid quenching with cooling rates of ca. 10^6 K/s, a technique developed in the 1960s [130], it is possible to suppress crystallization during solidification and to retain the amorphous structure of the melt (see also → Metallic Glasses). In this way, wires or strips of amorphous soft magnetic materials can be prepared directly from the melt [131–133]. The alloys contain iron, nickel, and cobalt as ferromagnetic elements (T), or mixtures of these, and crystallization-suppressing metalloids (X) such as silicon, boron, carbon, and phosphorus. Typical compositions lie in the range $T_{70-85}X_{15-30}$ [134].

The most conspicuous property of these amorphous alloys is that they are the first soft magnetic materials to exhibit high mechanical hardness ($HV_{0.2} = 700 - 1100$).

5.2.2.1. Amorphous Magnetic Materials

The amorphous soft magnetic materials, without crystal anisotropy and structural lattice defects, and the possibility to produce alloys free of magnetostriction were milestones in the development of soft magnetic materials. The magnetic values attained by these materials, in particular for dynamic applications, are excellent (see Table 15). Particularly favorable is the electrical resistance, which is about three times greater than that of crystalline materials, and the thinness of the ribbons resulting from the production process (15 – 50 µm). The high yield strength of metallic glasses, about 5 – 10 times greater than those of comparable crystalline materials, means that they are insensitive to plastic deformation,

which has advantages for use in magnetic heads or as magnetoelastic sensors [135].

Toroidal cores can be very easily wound from metallic glass ribbons after insulation of the surfaces, without the numerous forming and annealing steps that are necessary for crystalline materials. However, in the production of stampings the greater hardness of the amorphous alloys leads to 1000-fold faster wear of tools.

The magnetization process in amorphous soft magnetic alloys is determined by the magnetoelastic energy and the induced anisotropy. Internal mechanical stresses, resulting from inhomogeneous solidification [136], and surface roughness also play a role. The stresses can be relieved by thermal annealing below the crystallization temperature, whereas the state of the surface and the uniformity of the ribbon thickness depend mainly on the production process.

Magnetic tempering below the crystallization and Curie temperatures ($< 400-550\,°C$) allows the establishment of any desired hysteresis loop [137], as with crystalline Ni – Fe alloys. Noteworthy is that extremely rectangular or flat hysteresis loops are possible, with retention of the low coercive field strength.

Compared to soft ferrites, the classical materials for cores in high-frequency dynamic applications, the metallic glasses exhibit a better temperature dependence of the magnetic values and considerably higher saturation flux densities, which is important for the miniaturization of inductive components.

Amorphous Iron-Based Alloys. The amorphous iron-based alloys are composed of iron, silicon, boron, and/or carbon; examples are $Fe_{78}B_{19}Si_3$ and $Fe_{81}B_{13}Si_4C_2$. Since they are produced from cheap raw materials, they could be used for power applications in electrical technology.

In low-frequency applications, the amorphous iron-based alloys compete with grain-oriented electric sheet. Their losses are 60 – 70 % lower (0.15 – 0.2 W/kg at 1.4 T and 50 Hz) than those of conventional materials and their permeabilities are higher (see Fig. 50). However, the saturation flux density of 1.6 T is lower than that of crystalline Fe – 3 % Si, meaning that transformers can only be driven at up to ca. 1.4 T (see Fig. 51).

Figure 50. Core loss of two amorphous iron-based alloys at varying temperature
a) $Fe_{81}B_{13}Si_4C_2$ at 25 °C; b) $Fe_{81}B_{13}Si_4C_2$ at 100 °C; c) $Fe_{78}B_{19}Si_3$ at 50 °C; d) $Fe_{78}B_{19}Si_3$ at 100 °C

Figure 51. Comparison of the static $B(H)$ curves of an amorphous $Fe_{78}B_{13}Si_9$ alloy with that of grain-oriented electric sheet [138]
a) Amorphous $Fe_{78}B_{13}Si_9$, 30 µm thick; b) Grain-oriented silicon steel, 0.28 mm thick

An interesting potential use is in distribution transformers in the United States and Japan [139], [140]. Use of amorphous materials in all 35×10^6 distribution transformers in the United States could save 60×10^9 kW of energy per year [141]. However, the following properties make mass production of amorphous transformer cores unattractive: the stress sensitivity

of magnetostrictive iron-based alloys; their brittleness after annealing; the difficulty of punching the hard thin ribbons; and the resulting low filling factors of the cores. Nevertheless, amorphous distribution transformers with cross-shaped wound cores, covering the range up to 500 kVA, are now commercially available in the United States. The commercial viability has been demonstrated in product development and pilot series [140]. This application is, however, not of interest for Europe.

Figure 52. Variation of the magnetostriction constant λ_s and the saturation polarization J_s with the manganese and iron content of two amorphous cobalt-based alloys

Amorphous Cobalt-Based Alloys. The amorphous cobalt-based alloys have lower saturation flux densities than the iron-based alloys. Depending on the alloy composition, they are characterized by a small or almost vanishingly small magnetostriction constant λ_s ($|\lambda_s| < 10^{-7}$ possible) (Fig. 52). This leads to maximum values for the magnetic properties H_c, μ, and P_v and low stress sensitivity. At low working frequencies, the magnetic values are comparable to or better than those of Permalloys. At high driving frequencies (kHz range), the amorphous cobalt-based alloys are also superior to ferrites. These materials are therefore highly suited for highfrequency, high-tech applications [142]. The main disadvantage is the relatively high cost of these alloys resulting from their high cobalt contents. However, the ability to manufacture small, light cores, which is possible due to the high magnetic values, could contribute positively to the total cost of a complete inductive element.

Amorphous Nickel – Iron Based Alloys. These alloys contain approximately equal amounts of iron and nickel (ca. 40 at %), the rest being silicon and boron. Addition of molybdenum improves the thermal stability. The magnetic values lie between those of the amorphous iron- and cobalt-based alloys. The magnetostriction constant is ca. 10×10^{-6}. Figure 53 shows typical hysteresis curves, measured on toroidal cores in the tempered, as-produced condition and after two different magnetic temperings, which demonstrates the possibility of influencing the form of the hysteresis curve.

Figure 53. Static hysteresis curves of an amorphous $Fe_{39}Ni_{39}Mo_4Si_6B_{12}$ alloy subjected to various heat treatments [143]
a) Magnetic field annealing (longitudinal); b) Annealed (rapid cooling); c) Magnetic field annealing (transverse)

5.2.2.2. Nanocrystalline Magnetic Materials

In the 1980s a new group of soft magnetic materials with extremely fine grained structures was developed in Japan [144], [145]. They are produced by rapidly quenching an amorphous iron-based alloy (e.g., $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$), followed by controlled heat treatment above the crystallization temperature (ca. 510 °C). This leads to a homogeneous, ultrafine structure of α-FeSi with a grain diameter of 10 – 20 nm, whose formation is attributed to the addition of Cu and Nb [144]. These materials exhibit excellent soft

magnetic properties ($H_c < 1$ A/m, $\mu_i > 10^5$) because K_1 averages zero in the nanocrystalline lattice.

Figure 54. Temperature dependence of the saturation polarization J_s of amorphous and nanocrystalline $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$
Ordinate shows $J_s^{1/\beta}$ with $\beta = 0.36$.a) Nanocrystalline (1 h, 520 °C) b) Amorphous, as quenched

Figure 55. Annual world production of permanent magnets during the period 1960 – 1990

Figure 54 shows the saturation polarization $J_s^{1/\beta}$, with $\beta = 0.36$, as a function of temperature for a quenched probe and for a subsequently annealed probe [146]. After annealing, the Curie temperature rises from 320 to ca. 600 °C, while the saturation polarization at room temperature remains essentially unchanged. The kink in the $J(T)$ curve at ca. 320 °C indicates the presence of a second magnetic phase in the structure of the annealed probe. This is a grain-boundary phase, only a few atomic diameters wide, whose magnetic properties resemble those of the original amorphous phase (Table 19). This phase magnetically couples the nanocrystalline grains to one another. The form of the hysteresis curve of nanocrystalline materials can be influenced by magnetic annealing [147].

The nanocrystalline soft magnetic materials are innovative materials that combine the advantages of the amorphous iron- and cobalt-based alloys and should therefore have many applications, also in competition with classical soft magnetic materials.

6. Applications

6.1. Applications of Hard Magnetic Materials

From 1960 to 1990, the quantity of permanent magnets produced in the Western world increased from 16×10^3 t to 220×10^3 t (Fig. 55). The market share of the hard ferrites increased from ca. 27 % in 1960 to ca. 97 % in 1990. In 1990, ca. 4500 t AlNiCo magnets and ca. 2000 t of rare earth magnets (Sm – Co, Nd – Fe – B) were produced [84], [85], [148]. Figure 56 shows the division of the market for permanent magnets according to end use.

Apart from the magnetic properties and their temperature dependence, one of the most important factors in the choice of a magnetic material for a technical application is the cost. Therefore, because of their low cost, hard ferrites are used wherever small size and low weight are unimportant, whereas the rare-earth magnets are used when miniaturization is important. In the latter applications, the higher cost of the magnets is balanced to some extent by the smaller amounts of material required. AlNiCo magnetics are used in applications where high temperature stability of the magnetic properties is required (e.g., measuring instruments).

Table 19. Characterization of a nanocrystalline $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ alloy after tempering at 500 – 600 °C [146]

Phase	Composition	Grain size	Proportion of volume, %	T_c, °C	K_1
1	α-$FeSi_{20-23}$	10 – 20 nm	75 – 80	600	~ 0
2		intergranular phase $\sim$ 1 nm	20 – 25	320	

Figure 56. Distribution of the turnover from permanent magnets (ca. $\$ 2.0 \times 10^9$)

A comparison of commercial permanent magnets in terms of $(BH)_{max}$ values, relative costs, temperature behavior, and availability of raw materials is given in Table 20. Table 21 gives an overview of the most important applications of permanent magnets.

Electroacoustic transducers are among the best known applications of permanent magnets. About 30 % of the production of hard magnetic materials is used in loudspeakers, headphones, telephones, microphones, and phono cartridges. This section of the market is dominated by loudspeakers and headphones.

In magnetically driven machines, permanent magnetics provide the magnetic field in which an electrical conductor moves; this results in a force acting on the conductor and induces a potential difference across it. The performance of magnetically driven motors ranges from a few microwatts for quartz-controlled stepping motors in watches, through several kilowatts for large servo motors, and up to 100 kW for large electrical machinery. Magnetically driven motors are more efficient and safer than electrically driven motors.

A major use of permanent magnets in the field of magneto-mechanics are magnetic clutches, which allow contact-free transfer of force. For example, drives for chemical pumps can be manufactured in which the driving force is transferred from the driving half of the clutch through a wall to the other half of the clutch inside the pump. Advantages are that the driving force is transferred contact-free with virtually no losses; high revolution rates can be attained readily, and there are no problems with leakage.

Interesting uses of high-quality rare-earth magnets are found in plasma and particle physics. Permanent-magnet focussing and beam-guiding systems can be made which can act as replacements for energy consuming electrical or superconducting devices. Rare-earth magnets are used in high-intensity synchrotron radiation sources, which offer new and improved applications in medical science, material analysis, and solid-state physics. These devices contain a linear array of magnetic field amplitudes, produced by permanent magnets, which induces an electron beam to emit intensive, almost monochromatic synchrotron radiation [149].

6.2. Applications of Soft Magnetic Materials

Soft magnetic materials have uses in all areas of electrical engineering and electronics. The geometrical form of the magnetic core is of particular importance. These are used as tailor-made parts in magnetic systems or as inductive components. The main function of soft magnetic cores is to guide the magnetic flux as effectively as possible in magnet circuits, or to act as inducers in coil systems.

Table 20. Comparison of industrial permanent magnetic materials

Material	$(BH)_{max}$ value, kJ/m^3	Relative costs	Temperature behavior	Raw material base
Hard ferrite	30	1	satisfactory	very good
AlNiCo	50	4	very good	critical (Co)
SmCo 1 : 5	150	10	satisfactory	critical (Co), limited (Sm)
SmCo 2 : 17	200	7	good	critical (Co), limited (Sm)
1987 NdFeB	280	5	adequate	good
1992	280	3	satisfactory	good

Table 21. Overview of the most important applications of permanent magnets

Range of application	Examples	System function proportional to
Acoustic converters	loud speakers, head phones, telephone capsules, microphones, pickups	B
Motors and generators excited by permanent magnets, electromechanic converters	DC motors, EC motors, synchronous motors, stepping motors, generators, linear motors, torque transmitters	B
Mechanical systems using magnets	clutches, separators, magnetic conveying systems, bearings, transport systems	B^2
Magnetic field and focusing systems	dipoles, quadrupoles, hexapoles, undulators, wigglers, circulators, mass spectrometers, NMR systems	B

Solid magnetic components, produced by grinding or die pressing, are used for guiding magnetic flux, e.g., as pole shoes in electromagnets. Hot- and cold-rolled sheets, formed by stamping and bending, are used as pole pieces in electromechanical systems such as relays. The coercive field strength is the most important criterion for these applications. Casings formed by deep-drawing or by welding of sheets are used to protect sensitive measurement systems, such as automobile tachometers and computer monitors in industrial use, from stray magnetic fields.

Dynamic applications require laminated cores to minimize eddy current losses. High-permeability laminated cores are used in electrical safety applications, e.g., false current safety switches. Core sheets and compacted core sheets are used as in signal engineering. Furthermore, numerous inductive components, such as transformers, repeater coils, transducers, and chokes, require magnetic cores whose dimensions and electrical and magnetic properties are designed for the various operating conditions.

Table 22 gives an overview of the soft magnetic materials and their uses.

Table 22. Uses of soft magnetic materials

Material	Lamellated magnetic core		Mouldings	
	Uses	Delivery form	Uses	Delivery form
Classical soft magnetic materials				
Pure iron	radio interference suppression coils	combination cores with NiFe tapes	relays, motors, yokes for electromagnets	punched bent workpieces, finished annealed hardware, semifinished products
Iron – silicon				
nonoriented	rotating machines	core sheets (punched)	relays, motors	punched bent workpieces, finished annealed hardware, semifinished products
grain-oriented	transformers	tape (wound) cores		
Iron – nickel				
E 5			temperature compensation of permanent magnet systems	punched workpieces, finished annealed semifinished products
E 4	transformers for communication engineering, pulse transformers, throttles	core sheets (punched), tape cores/tape-wound cores	screenings, relay and magnet systems, pole screen and other flux-guiding workpieces	deep-drawing workpieces, connecting workpieces, finished annealed hardware, semifinished products (punched, sheets)
E 3	current transformers, throttles, transformers for communication engineering	toroidal tape cores, tape cores with air gap, tape cores, core sheets, laminated cores	relays, yokes/rotors, measuring systems	finished annealed hardware, semifinished products
E 2	current transformers, thyristor protection throttles	toroidal tape cores		
E 1	current transformers, transformers for communication engineering	toroidal tape cores, core sheets, laminated cores	screenings, highly sensitive relays	deep-drawing workpieces, connecting workpieces, semifinished products (plates, sheets), punched bent workpieces
Iron – cobalt	rotating machines, transformers	core sheets (punched), tape cores	flux-guiding workpieces	finished annealed hardware, semifinished products
Soft ferrite			inductive structural components	standardized mouldings
Modern soft magnetic materials				
Powder-bound composite			rotating machines, throttles, transformers	pressed and mechanically-worked stator workpieces, toroidal core (pressed), coated cores
Amorphous				
Fe-based	transformers	(toroidal) tape cores		
Co-based	transformers, throttles, sensors	toroidal tape cores		
Nanocrystalline	transformers, throttles	toroidal tape cores

1. Maleic Acid

Maleic acid [*110-16-7*], $C_4H_4O_4$, *cis*-butenedioic acid, M_r 116.07, does not occur naturally. It was first produced by Pelouze in 1834 by heating malic acid. Maleic acid became industrially important after the Barrett Co. in the United States successfully obtained the acid in 1919 by catalytic gas-phase oxidation of benzene. Maleic acid has been available commercially since 1928; maleic anhydride, since 1933.

R = H: Maleic acid
R = CH_3: Citraconic acid

R = H: Fumaric acid
R = CH_3: Mesaconic acid

Maleic acid itself is not very important economically. Small amounts are used for maleinate resins and, as maleic acid esters, for copolymers.

Physical Properties. The acid crystallizes in the form of monoclinic prisms. Other physical properties are listed below:

mp	130.5 °C
d_{20}^{20} (solid)	1.590
Heat of formation	− 788.3 kJ/mol
Heat of combustion	− 1358.9 kJ/mol
Solubility in 100 g of water	
at 25 °C	78.9 g
at 40 °C	112.3 g
at 60 °C	148.8 g
at 97.5 °C	392.6 g
Dissociation constants in water	
at 25 °C	K_1 1.14×10^{-2}
	K_2 5.95×10^{-7}

Chemical Properties. Maleic acid is very reactive at both its carboxyl groups and its double bond. Thus, on heating above 100 °C, water is eliminated with the formation of maleic anhydride. On further heating–preferably with the addition of catalysts–decarboxylation occurs with the formation of acrylic acid. Maleic acid also undergoes all normal reactions of *carboxylic acids,* such as esterification and amidation, but it does not form an acid chloride.

Examples of reactions involving the *double bond* are addition of water to form malic acid at elevated temperature and pressure; reaction with ozone to form glyoxylic acid; addition of halogens to form compounds such as dichlorosuccinic acid; and catalytic hydrogenation to succinic acid. Isomerization to fumaric acid occurs slowly already at temperatures as low as 100 °C; in the presence of a catalyst it proceeds almost quantitatively even at 60 °C.

Production. Maleic acid is generally obtained by heating maleic anhydride in a small

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a16_053

amount of water. After the reaction mixture is cooled, the supernatant mother liquor is separated and the solid product is dried in vacuo. The mother liquor is diluted with water and returned to the hydration stage. It can, however, also be passed to the dehydration stage of maleic anhydride production (see Section 2.2.2), which avoids the problem of effluent purification. The apparatus must be made of corrosion-resistant steel.

Occasionally, maleic acid is also obtained directly from the wash water of maleic anhydride production; energy required for dehydration to the anhydride is thus saved. However, the wash water must first be purified with active charcoal; the charcoal must then be removed and disposed of. Furthermore, the purified solution must be concentrated in vacuo because fumaric acid is formed at elevated temperature and the chrome – nickel steel apparatus corrodes above 80 °C. Enriched wash water from *o*-xylene and naphthalene oxidation plants (phthalic anhydride production) is also used as a starting material for this process, as well as for the production of fumaric acid and maleic anhydride.

Quality Requirements. Maleic acid must meet stringent quality requirements. White crystals with a maximum fumaric acid content of 0.1 – 0.2 % are required, and the water content should be < 0.5 %.

2. Maleic Anhydride (MA)

Maleic anhydride [*108-31-6*], $C_4H_2O_3$, 2,5-furandione, M_r 98.06, has considerable industrial importance, in contrast to maleic acid.

Maleic anhydride

2.1. Properties

Physical Properties. Maleic anhydride crystallizes as orthorhombic needles. The most important physical properties may be summarized as follows:

mp	52.85 °C
bp (101.3 kPa)	202.0 °C
Heat of combustion	− 1391.2 kJ/mol
Specific heat (liquid)	− 1.67 kJ mol^{-1} K^{-1}
Heat of evaporation	54.8 kJ/mol
Heat of fusion	13.66 kJ/mol
Solubility in xylene (29.7 °C)	163.2 g/L

Vapor pressure of maleic anhydride at various temperatures:

t, °C	44.0	78.7	111.8	135.8	179.5	202.0
p, kPa	0.13	1.33	5.33	13.33	53.33	101.33

Chemical Properties. Maleic anhydride reacts readily with water to form maleic acid. At low temperatures, addition of alcohols leads to the formation of semiesters, whereas at elevated temperature in the presence of esterification catalysts, water is eliminated with the formation of diesters. Addition of ammonia or amines to maleic anhydride results in formation of the corresponding semiamides, which can be converted by elimination of water into cyclic imides.

The double bond in maleic anhydride is also extremely reactive. Addition of halogens leads to the formation of dihalogenated succinic anhydrides or mono- and dihalogenated maleic anhydrides, depending on reaction conditions. Hydrogenation yields succinic anhydride, 1,4-butanediol, tetrahydrofuran, or butyrolactone, depending on conditions.

Alkenylsuccinic anhydrides are formed by addition of olefins. Maleic anhydride undergoes Diels – Alder reactions with conjugated dienes. The anhydride is also suitable for homopolymerization and copolymerization. A summary of the reactions of maleic anhydride is given in [1], [2].

2.2. Production

Maleic anhydride is produced industrially by catalytic oxidation of suitable hydrocarbons in the gas phase. Benzene used to be the predominant starting material, but in recent years oxidation of C_4 hydrocarbons has become increasingly important; the C_4-based capacities are continually increasing.

2.2.1. Oxidation of Benzene

To produce maleic anhydride (see Fig. 1), benzene is added to a preheated airstream so as to form a largely homogeneous mixture. If a large excess of air is used, the lower ignition limit of the mixture is not reached in the majority of methods.

Tubular reactors with a multiplicity of parallel vertical tubes of ca. 25-mm diameter are used for conventional fixed-bed methods. Reaction gas passes through the tubes over the catalyst, the process pressure being adjusted to an optimum value of 0.15 – 0.25 MPa. Supported catalysts are used, where an "active mass" of V_2O_5 and MoO_3 is applied on an inert carrier. The lifetime of the catalysts is up to four years and depends mainly on the operating temperature in the reactor; a uniform, interference-free operation; and the purity of starting materials. Both the desired main reaction

$$C_6H_6 + 4\,1/2\,O_2 \rightarrow C_4H_2O_3 + 2\,CO_2 + 2\,H_2O$$

$$\Delta H = -1875\ \text{kJ/mol}$$

and the undesirable secondary reaction of combustion to carbon monoxide, carbon dioxide and water are strongly exothermic, and "hot spots" of 340 – 500 °C occur in the catalyst. A considerable amount of heat is produced during the reaction. Approximately 27 MJ of heat must be dissipated per tonne of reacted benzene, which corresponds to almost 10 t of saturated steam; in practice, ca. 80 % of the steam can be utilized.

Heat is dissipated primarily by eutectic salt melts circulating around the reactor tubes. The hot salt melts are cooled with water in a secondary heat exchanger. Only part of the generated steam can be used in MA production. In many cases, excess steam–unless it can be utilized in other operations–is used to drive air compressors. The reaction can be optimized with regard to MA yield by means of the accurately adjustable (± 0.5 °C) salt bath temperature.

In a typical conversion of 100 mol benzene, 73 mol is oxidized to maleic anhydride and 23 mol is "burned." Unreacted benzene (4 mol) can largely be recovered by a subsequent adsorption step (e.g., with activated charcoal) and reused. Processes that involve recycling the major portion of reaction gas after MA separation are described in some patents; up to the present, they have not been used on an industrial scale [3], [4].

Separation of Crude Maleic Anhydride. After leaving the reactor, the gas mixture is initially cooled to 150 – 160 °C so that neither MA nor water condenses. The waste heat is utilized further. Different routes can then be used for further processing.

Partial Condensation. In liquid partial condensation the melting point of MA is the lower temperature limit. The reaction gas is cooled to ca. 55 °C in "partial condensers" [5] (e.g., bundles of vertical tubes 20 – 50 mm in diameter); MA condenses and can be removed as liquid from the collecting vessel. Discharge should occur as quickly as possible [6] because prolonged contact of the liquid product with the water-containing reaction gas leads to the formation of fairly large amounts of maleic acid. In this way, 40 – 60 % of the MA contained in the reaction gas can be separated; the remainder is normally washed out with water as maleic acid and processed further to MA (see Section 2.2.2).

Separation by Water Scrubbing. In principle, all the MA contained in the reaction gas can also be recovered as maleic acid solution by water scrubbing. To obtain MA from this solution, the acid must be dehydrated. Because of the associated high energy requirement, this method is justified only to obtain MA from reaction gases with a high water content, such as occur in the C_4 oxidation.

For separation by washing with organic solvents, see Section 2.2.3.

2.2.2. Dehydration of Aqueous Maleic Acid Solutions

Maleic anhydride can be obtained by dehydration from the maleic acid solutions that are formed by washing the reaction gas with water (see Fig. 1). Above 150 °C even small amounts of alkali in the wash solution can decompose the resultant crude MA to decarboxylation products [7]; thus, alkali-free wash water must be used.

Temperatures above 100 °C are required for dehydration of maleic acid ($\Delta H = +34.88$ kJ/mol). A reaction rate sufficient for industrial processes is, however,

Figure 1. Plant for production of maleic anhydride by benzene oxidation
a) Reactor; b) Salt bath cooler; c) Partial condenser; d) Acid scrubber; e) Alkali scrubber; f) Dehydration column; g) Phase separator

achieved only above 130 °C. Isomerization of maleic acid to fumaric acid occurs concurrently ($\Delta H = -23.2$ kJ/mol).

Fumaric acid decomposes only when heated above 230 °C, without forming significant amounts of MA. The isomerization reaction must therefore be suppressed in the dehydration of maleic acid; this is achieved by having as short a residence time as possible at elevated temperature.

Entraining Agent Method. Aqueous maleic acid solution is added to the upper half of a distillation column (Fig. 1, f) whose bottom contains a boiling MA – entraining agent mixture. Aromatic hydrocarbons (e.g., xylene) are generally used as entrainers.

The entraining agent together with the water leaves the head of the column as an azeotropic mixture. Then it is separated as the organic phase in separator (g) and refluxed to the head of the column. The aqueous phase is returned to the reaction gas scrubber (d) of the oxidation plant [8].

The bottom product (MA, 10 – 40 % entraining agent, 1 – 5 % maleic acid, 1 – 3 % fumaric acid) is distilled to yield pure MA (see Section 2.2.4). The process is performed continuously as well as batchwise.

Thermal Process Without Entraining Agent. The thin-layer evaporator technique has been used for some time for thermal dehydration of aqueous maleic acid solutions. By this technique the water can be separated as steam, and the residence time of maleic acid at 150 – 200 °C is kept very short. Conditions for isomerization thus exist for only a short time, and only a small amount of fumaric acid is formed (1 – 3 %). Several thin-layer units are arranged in sequence [9], [10]. The MA separated as liquid in the partial condenser (see Fig. 1) is also fed to the second stage of this plant to dehydrate residual maleic acid (1 – 5 %). The 99 % MA obtained is distilled to yield pure product (see Section 2.2.4).

Fumaric acid and high-boiling residues are discharged from the bottom of the last thin-layer evaporator.

These continuously operating plants must be shut down relatively frequently for cleaning.

2.2.3. Oxidation of C_4 Hydrocarbons

Processes for the oxidation of C_4 hydrocarbons involve mainly the use of *n*-butane or *n*-butane – *n*-butene mixtures with a high paraffin content. The following types of process have been developed or are in the developmental stage:

fixed-bed process
fluidized-bed process
transport-bed process

In the United States the fixed-bed process with *n*-butane has been the only MA route used commercially since 1985; it is employed to a small but increasing extent in other parts of the world. With improved methods and sufficient raw material availability, C_4 oxidation has become increasingly important; the low raw material price has had a decisive influence on the economy of this process.

With C_4 oxidation lower conversion rates (80 %) and selectivities (70 %) contrast theoretically higher weight yields (+ 34 wt % compared to benzene oxidation) so that finally, weight yields for benzene and C_4 oxidation are comparable (ca. 95 wt % MA). Since the recovery of unreacted C_4 hydrocarbons is substantially more difficult than with benzene, reaction waste gases from C_4 oxidation must be passed to an incineration unit.

Fixed-Bed Process. In the fixed-bed process the catalyst is embedded in tubular reactors, similar to benzene oxidation. Since the publication of the first U.S. patents catalysts based on vanadium and phosphorus oxides (V – P – O catalysts) have mainly been used [11–15].

The concentration of hydrocarbons in the feed gas to the reactor is kept just below the explosion limit of 1.8 mol % [corresponding to 45 g/m^3 (STP) air] in the commercial fixed-bed process. Conversion at the catalyst in the selective reaction proceeds as follows:

$$C_4H_{10} + 3\,1/2\,O_2 \rightarrow C_4H_2O_3 + 4\,H_2O$$

$$\Delta H = -1260\ \text{kJ/mol}$$

Because of the increased formation of water per formula conversion compared to benzene oxidation, with C_4 oxidation only a fairly small amount of MA can be directly liquefied from the reaction gas by partial condensation. The larger proportion (65 – 70 %) is washed out as maleic acid in a subsequent water scrubber and must be dehydrated, with a high energy input.

In a modification of the water wash, MA contained in the reaction gas is alternatively absorbed by organic solvents [16–19]. More than 98 % of the anhydride can be absorbed in this way, without noticeable amounts of maleic acid being formed. The solvent – anhydride mixture is then subjected to fractional distillation, in which MA is distilled from the high-boiling solvent and the latter is returned to the absorption column.

Fluidized-Bed Process. The fluidized-bed process has the advantage of a particularly uniform temperature profile (without "hot spots"). A uniform temperature profile is the necessary precondition for high reaction selectivity, it is, however, offset to some extent by intensive remixing of the products as a result of fluidization. A particular problem of this process is mechanical stress on the catalyst (V – P – O), its abrasion, and erosion at the heat-dissipating surfaces. On the other hand, the fluidized bed constitutes an extremely effective flame barrier, with the result that the process can operate at higher C_4 concentrations (i.e., within the explosion range) than the fixed-bed process. This results in process engineering advantages plus a considerably smaller investment for fluidized-bed technology [20].

The *ALMA process* (Alusuisse, Lummus) is currently the most technically advanced process; it combines a fluidized-bed reactor with a nonaqueous processing unit [18], [19].

In October 1988 a 10 000-t/a MA plant [21] combining fluidized-bed technology with an aqueous processing unit has come on stream at MTC Sohio, Japan.

Transport-Bed Process. The transport-bed process developed jointly by Monsanto and Du Pont is at the trial stage [22], [23]. The process involves two reactors: in the first, spent catalyst (V – P – O) removed from C_4 oxidation is regenerated by atmospheric oxygen. Regenerated (oxidized) catalyst is separated from the oxygen-containing gas; then it passes, with the addition of butane, to the second reactor. Here, catalytic conversion to MA takes place, the reaction being carried out with virtual exclusion of atmospheric oxygen and simply with the amount of oxygen transferred by the catalyst itself. A high selectivity of MA formation (75 mol %) is said to be achieved under the quasi-stoichiometric conversion conditions of this process, which also largely prevents remixing of reaction gases.

2.2.4. Purification

Batchwise Distillation. Batchwise distillation is the conventional method for processing

crude MA. Directly separated MA, as well as mixtures from entraining agent dehydration, are added to the batch distillation column. The mixture is distilled under total reflux conditions until the remaining maleic acid is dehydrated. The small amounts of water eliminated are separated from the recirculating entraining agent (xylene). The entrainer is then distilled, and MA is recovered by distillation in vacuo. Batch stills of 50–150-m^3 capacity and distillation columns with 10–20 trays are used.

Continuous Distillation (see Fig. 2). For large-capacity MA plants, processing by continuous distillation is both possible and economical [24], [25]. The mixture of directly separated and crude MA obtained by dehydration is continuously "postdehydrated". Residual xylene is separated in a column (f), and pure MA is finally distilled from the top of a second column (g).

2.2.5. Byproducts, Construction Materials, Effluent, and Discharge Air

Benzene Oxidation.

Byproducts. Benzoquinone, formaldehyde, and formic acid occur in small amounts as byproducts of benzene oxidation.

Construction Materials. Directly condensed crude MA containing 1–5 % maleic acid can be stored at ca. 60 °C in normal steel vessels. Special stainless steel is essential in the "wet" region of the plants (i.e., for scrubbers, vessels containing maleic acid solution, dehydration column, and apparatus used for postdehydration). The partial condensers should preferably also be made of special stainless steel. For reasons of quality, stainless steel is used for the pure MA distillation columns.

C_4 Oxidation. Because acetic, acrylic, and crotonic acids, etc., are formed as byproducts of C_4 oxidation, a suitable special stainless steel must be chosen with particular care for the relevant equipment.

Environmental Protection. The MA plants can be operated almost without any acid effluent if aqueous maleic acid solutions from the dehydration stage are recycled. Byproducts are contained in the distillation residue, which is normally combusted.

Environmental legislation differs very much in various countries. In the Federal Republic of Germany the TA Luft (Clean Air Regulations) was revised in 1986. The emission of benzene, which is classified as a carcinogen, must not exceed 5 mg/m^3 in waste gas from benzene oxidation [26]. This necessitates installation of a combustion unit downstream of the benzene adsorption stage, as in C_4 oxidation plants [27].

2.3. Quality, Storage, and Transportation

Quality Specifications. A typical specification for pure MA includes the following:

mp	52.5 °C (min.)
Acid number	1140 mg KOH/g (min.)
Purity	99.7 wt % (min.)
Melt color index	20 APHA (max.)
Ash content	10 ppm (max.)
Iron content	5 ppm (max.)

Storage of Pure MA. Pure MA in the molten state at 55–65 °C is stored in stainless steel or pure aluminum vessels. It can be stored for several weeks in an inert-gas atmosphere without any change in quality.

Commercial Forms and Transportation.

Liquid MA is transported over large distances at 60–80 °C in well-insulated road tankers or tank containers. The vessels are provided with heating devices.

Solid MA is dispatched in the form of pastilles and briquettes weighing 0.5–20 g. Because of their high dust content, flakes are rarely produced. Multiply paper bags with welded polyethylene liners or bags of strong polyethylene film are normally used as packaging. Solid MA can be stored for several months in this packaging in a cool, dry place.

Maleic anhydride is included in the list of dangerous substances and preparations according to the EEC Directive 67/548/EEC and GefStoffV and must be specially packed and identified. However, on the basis of the most recent toxicological investigations, the identification according to GefStoffV [28] should be amended and amplified as follows [29]:

Figure 2. Continuously operating plant for production of pure maleic anhydride
a) Condenser; b) Separating vessel; c) Column; d) Postdehydration; e) Intermediate tank; f) *o*-Xylene column; g) Pure MA column; h) Cooler; i) Colorimeter; j) Pure MA vessel

Danger symbol	C (corrosive)
R	22 – 34 – 42/43
S	22 – 28 water – 39

The hazard classification for the transport of MA are as follows:

IMDG Code (GGVSee)	Class 8
GGVS/GGVE, ADR/RID	Class 8, no. 31 c
UN no.	2215

2.4. Uses

Because of its properties as a dicarboxylic anhydride with a double bond, MA can be used for both polycondensation and polyaddition. Polyester and alkyd resins, lacquers, plasticizers, copolymers, and lubricants are the most important technical end products. Examples of industrially important copolymers are: MA – styrene (for engineering plastics) and MA – acrylic acid (used in the detergent industry). Polyester and alkyd resins, in particular, are used in the production of fiberglass reinforced plastics, in the construction and electrical industries, and in pipeline and marine construction.

Tetrahydrophthalic anhydride is formed by a Diels – Alder reaction with butadiene; hydrogenation of the anhydride yields hexahydrophthalic anhydride. Methylhexahydrophthalic anhydride is obtained in a similar manner from isoprene and MA. These products are used as anhydride curing agents for epoxy resins.

Smaller amounts of MA are used in the production of pesticides (captan, malathion) and growth inhibitors (maleic acid hydrazide). Surfactants are produced from maleic acid esters by reaction with sodium hydrogen sulfite. When added to drying oils, MA reduces the drying time and improves the coating quality of lacquers.

3. Citraconic and Mesaconic Acids

In 1881 Anschütz obtained mesaconic [*498-24-8*], 2-methyl-*trans*-2-butenedioic acid and citraconic acid [*498-23-7*] (2-methyl-*cis*-2-butenedioic acid) for the first time by distilling citric acid. Citraconic acid forms an inner anhydride (citraconic anhydride [*616-02-4*], 3-methyl-2,5-furandione, *mp* 7 °C, *bp* (4 kPa) 109 °C, $d_4^{15.7}$ 1.2469), analogously to maleic acid. Citraconic anhydride is interesting particularly because of its low melting point (easier handling at lower temperature).

Many attempts have been made to develop industrial processes for obtaining *citraconic anhydride*, including its preparation from citric acid (1905), and gas-phase oxidation of alkyl-substituted olefins [30], methylbutanols [31], or mesityl oxide [32]. In the gas-phase oxidation of *o* -xylene, ca. 2 – 4 t of citraconic anhydride is formed per 1000 t of phthalic anhydride. Citraconic anhydride is present as citraconic acid after water washing. Three processes have been developed to isolate citraconic anhydride [33–35]. Its synthesis from succinic anhydride and formaldehyde has been proposed [36].

With regard to its industrial use, citraconic anhydride is frequently mentioned with MA in patents. Substitution of citraconic acid for MA, however, does not impart any special properties to the products. Citraconic anhydride is useful simply in producing liquid curing agents for epoxy resins: Diels – Alder synthesis with isoprene yields a nonhygroscopic curing agent that is liquid at room temperature [37].

4. Fumaric Acid

Fumaric acid [*110-17-8*], *trans*-butenedioic acid, M_r 116.07, occurs widely in nature. It received its name from WINCKLER, who isolated it from fumitory (*Fumaria officinalis*) in 1832. Subsequently, it was isolated many times under the names boletic acid, glaucinium acid, and lichen acid, and in 1834 it was described by PELOUZE who called it paramaleic acid. Fumaric acid is currently produced on an industrial scale, although it is less important than maleic anhydride.

Physical Properties. Fumaric acid crystallizes in the form of monoclinic prisms. Important physical properties are summarized below:

mp	286 – 287 °C (closed tube)
d^{25} (solid)	1.635
Heat of sublimation (92 °C)	136.1 kJ/mol
Dissociation constants in water	
	K_1 9.57×10^{-4}
	K_2 4.13×10^{-5}
Solubility in 100 g of water	
at 15.5 °C	0.428 g
at 100 °C	9.97 g

Chemical Properties. Fumaric acid sublimes without decomposition at 200 °C or slightly higher. Above 230 °C, however, it decomposes with the formation of maleic anhydride, water, and a considerable amount of residue. Addition of phosphorus pentoxide promotes the formation of maleic anhydride.

Its other chemical properties resemble those of maleic acid. Reactions proceed considerably more slowly, however, due partly to the lower water solubility of fumaric acid. In contrast to maleic acid, fumaric acid forms an acid chloride.

Production (see Fig. 3). Maleic acid or maleic anhydride, especially the maleic acid-containing wash water from the production of maleic anhydride or phthalic anhydride, serves as starting material for the manufacture of fumaric acid. The maleic acid concentration should be at least 30 %. Maleic acid is converted almost quantitatively by thermal [38] or catalytic isomerization into the sparingly soluble fumaric acid, which is recovered by filtration. Various substances have been proposed as catalysts: mineral acids (e.g., hydrochloric acid) [39]; sulfur compounds such as thiocyanates, thiazoles, thiosemicarbazides, thioureas; or bromine compounds in combination with peroxides (e.g., persulfate) [40]. Thiourea is most commonly used in practice [41].

The maleic acid-containing wash water contains impurities that can affect quality and yield. This problem can be largely avoided (1) by thermal pretreatment of the wash water [42], (2) by adding urea [43] if thiourea is used as catalyst, and (3) by addition of sulfites or passaged of sulfur dioxide [44] and addition of mineral acids [45]. The crude fumaric acid obtained is purified by recrystallization from water, combined with purification by active charcoal. Losses during purification are ca. 10 %.

Fumaric acid production is generally carried out batchwise, although continuous processes are also known. If hydrogen chloride does not have to be added, an apparatus made of corrosion-resistant austenitic steel is satisfactory. Disposal of the mother liquor from the isomerization stage, which in addition to soluble impurities also contains the isomerization catalyst, is especially difficult. One possibility is to combust the effluent.

In the United States, fumaric acid is also produced by fermentation of monosaccharides or starch with selected fungal cultures (*Mucor, Aspergillus, Rhizopus*) [46].

Uses. Fumaric acid is often used instead of maleic acid to produce polyesters and copolymers. A nearly identical mixture of *trans*- and *cis*-dicarboxylic acids is formed by isomerization during the preparation of these products [47], regardless of whether maleic or fumaric acid is used as starting material. Fumaric acid is often preferred because of its innocuous nature.

Figure 3. Plant for production of fumaric acid from aqueous maleic acid solutions
a) Isomerization vessel; b) Centrifuge; c) Dissolving tank; d) Filter; e) Crystallizer; f) Dryer; g) Silo

On the other hand, special effects are observed when fumaric acid is used, e.g., greater hardness of certain resins [48].

Because it is nontoxic, fumaric acid is used in the food industry, e.g., as an acidulant in baking powders and beverages, for which purpose particularly stringent requirements are placed on purity (U.S. Food Chemicals Codex). Fumaric acid (Fumaril) and iron(II) fumarate are used as special additives for animal feeds [49].

5. Toxicology

Maleic Anhydride. In aqueous solution, maleic anhydride slowly hydrolyzes to maleic acid; accordingly, the toxicological properties of the anhydride are in part determined by the toxicological activity profile of maleic acid. The *acute toxicity* is characterized by LD_{50} values of 481 mg (rat, oral), 465 mg (mice, oral), 2620 mg (rabbit, percutaneous), and 390 mg (guinea pig, oral) per kilogram of body weight [50]. The main acute toxic effects of this compound are its powerful local irritant and corrosive action on the skin, mucous membrane, and eyes. At a concentration of 1.5 – 2 ppm, nasal irritation was observed in workers after 1 min, and irritation of the eyes after 15 – 20 min [51]. Concentrations > 2.5 ppm are extremely irritant. Asthmatic symptoms may occur after long-term exposure to maleic anhydride concentrations > 1.2 ppm [52]. In addition to its acute irritant action, maleic anhydride is also characterized by a strongly sensitizing action, which has been observed experimentally in guinea pigs as well as in humans [52], [54].

No *systemic* toxic effects were observed in a 6-month inhalation exposure of rats, hamsters, and monkeys to up to 2.4 ppm of maleic anhydride [55]. Animal experimental studies did not reveal any evidence of a carcinogenic, teratogenic, or reproductive – toxicological action of maleic anhydride [55–57].

The MAK and TLV – TWA values were based on the acute irritant and sensitizing action of maleic anhydride and are 0.2 and 0.25 ppm, respectively [52], [53].

Maleic Acid. As an acid, the toxicological activity of maleic acid is characterized by marked irritant and corrosive action on the skin, mucous membrane, and eyes. A 20 % aqueous solution produced a mild and reversible skin irritation in humans [58]. Lower concentrations (< 5 %) are sufficient to produce serious ocular irritation [59]. Animal experiments confirm that the local irritant action is the most prominent toxicological feature of maleic acid. The *acute* oral and dermal toxicity is characterized by LD_{50} values of 708 mg (rat, oral), 2400 mg (mouse, oral), 1560 mg (rabbit, dermal), and > 1000 mg (guinea-pig, dermal) per kilogram of body weight [60].

Kidney damage has been observed as a *systemic* toxic action of maleic acid. Morpholog-

ical – functional changes in the kidneys were produced by intraperitoneal injection (100 – 350 mg/kg; rats, dogs) and also by 1-h inhalation exposure to ca. 720 mg/m^3 (rats) [61]. The damage to distal and proximal tubular resorption produced by maleic acid is reminiscent of the known (congenital or acquired) Fanconi syndrome in humans [62], [63]. This damage seems to be caused by the interaction of maleic acid with glutathione in tubular renal cells, leading to intolerable concentrations of free radicals and peroxides [64]. In addition to the resultant cellular damage, maleic acid appears to affect Na^+ and H^+ ion transport in the proximal tubes [65]. After chronic exposure of male rats (250, 500, 750 mg kg^{-1} d^{-1} for up to two years), an increased mortality as well as kidney damage and delayed growth was observed in all dosage groups [66]. Liver and testicular damage has also been found in the highest dosage group. No signs of *carcinogenic activity* of maleic acid were discovered with this long-term dosage, which however was not designed as a carcinogenicity study. No *genotoxic effects* were observed in the Ames test, with or without metabolizing fractions [67].

Fumaric Acid. Fumaric acid is a naturally occurring intermediate of the tricarboxylic acid cycle and is used as a food additive [68]. Accordingly the compound is found to be practically nontoxic in acute toxicity tests. An oral LD_{50} value of 10 g/kg of body weight was measured in rats, and in rabbits 20 g/kg of body weight applied dermally was not lethal [69]. In humans, no changes in the blood and urine parameters or in liver function were found after administration of 8 mg of fumaric acid per kilogram of body weight per day for one year [70]. Experimental investigations did not reveal any evidence of genotoxic [67], [71], carcinogenic [70], [72], or reproductive – toxicological [70] activity. The toxicological evaluation of fumaric acid is thus based primarily on the local irritant action on contact with the skin, mucous membrane, and eyes. In this respect, fumaric acid is classified as slightly irritant to the skin and moderately irritant to the eyes and mucous membranes.

1. Introduction

Three-carbon 1,3-dicarboxylic acid derivatives (malonic acid, malonates, cyanoacetic acid, cyanoacetates, and malononitrile) are widely used in industry for the manufacture of pharmaceuticals, agrochemicals, vitamins, dyes, adhesives, and fragrances. The common feature of malonic acid and its derivatives is the high reactivity of the central methylene group. Due to the increasingly electron-withdrawing character of the substituents, the acidity of the hydrogen atoms in the 2-position increases in the order malonates < cyanoacetates < malononitrile. Therefore, all these compounds undergo reactions typical of 1,3-dicarbonyl compounds. For example they are easily alkylated or arylated, undergo aldol and Knoevenagel condensations, and they can be used for the synthesis of pyrimidines and other nitrogen heterocycles.

Malonic acid and derivatives are basically all produced by reaction of a two-carbon building block with a one-carbon unit (Fig. 1). Thus, cyanoacetates are prepared from sodium chloroacetate and sodium cyanide, followed by acidification and subsequent esterification. Malonates are produced either by a cobalt-catalyzed alkoxycarbonylation of chloroacetates with carbon monoxide in the presence of alcohol, or by hydrolysis of cyanoacetic acid followed by esterification. For the production of malononitrile, the continuous high-temperature reaction of cyanogen chloride and acetonitrile has almost totally replaced the former synthesis, based on dehydration of cyanoacetamide (**1**).

2. Malonic Acid

Physical Properties. Important physical properties of malonic acid (propanedioic acid, methanedicarboxylic acid) are listed in Table 1. Its pK_a values are 2.83 and 5.70. Malonic acid forms a colorless hygroscopic solid which sublimes in vacuum with some decomposition. Its solubility is 139 g in 100 g of water (at 22 °C) and 15 g in 100 g of pyridine (at 15 °C). Malonic acid is only slightly soluble in ethanol and diethyl ether, and is insoluble in benzene.

Chemical Properties. Malonic acid is found in small amounts in sugar beet and green wheat, being formed by oxidative degradation of malic acid. Reaction with sulfuryl chloride or bromine gives mono- and dihalogenated malonic acid, whereas treatment with thionyl chloride or phosphorus pentachloride leads to mono- or diacyl chloride. When heated with phosphorus pentoxide, malonic acid does not form an anhydride but rather carbon suboxide, a toxic gas that reacts violently with water to reform malonic acid. On heating the free acid above 130 °C, or an aqueous solution above 70 °C, decomposition to acetic acid and carbon dioxide takes place. The mono- and dianion of malonic acid are more stable. In aqueous solution the monosodium salt decomposes above 90 °C and the disodium

** *mp* (decomp.).

salt above 130 °C [1]. These mild decarboxylation conditions combined with its ability to undergo Knoevenagel condensations makes malonic acid a useful reagent for the synthesis of α,β-unsaturated carboxylic acids. Thus cinnamic acids are formed by reaction of malonic acid with benzaldehyde derivatives, and acrylic acids from malonic acid and aliphatic aldehydes [2]. Finally, platinum complexes of malonic acid and its derivatives have been investigated as antitumor agents [3, 4].

Production. The industrial production of malonic acid is less important than that of the malonates. Malonic acid is usually produced by hydrolysis of cyanoacetic acid [5, 6] or by acid saponification of malonates [7–9].

Alternative more recently reported methods for the preparation of malonic acid are the ozonolysis of cyclopentadiene [*542-92-7*] [10], the palladium-catalyzed air oxidation of 1,3-propanediol [11], the platinum group metal-catalyzed oxidation of 3-hydroxypropionaldehyde or 3-hydroxypropionic acid [12] and the use of malononitrile as a substrate for a nitrilase [13].

Uses. Malonic acid is used for the introduction of an acetic acid moiety under mild conditions by Knoevenagel condensation and subsequent decarboxylation. Examples include the preparation of cinnamic acid, used for the production of the anti-inflammatory cinmetacin [*20168-99-4*] (**2**) [14, 15] and 3,4,5-trimeth-

oxycinnamic acid, the key intermediate of the vasodilators cinepazet [*23887-41-4*] (**3**, R = OEt) [16] and cinepazide [*23887-46-9*] (**3**, R = 1-pyrrolidinyl) [17]. The fragrance γ-nonanoic lactone [*104-61-0*] (**4**) is available by Knoevenagel condensation of malonic acid with heptaldehyde [*111-71-7*] followed by ring closure [18].

2

3

4

Derivatives. *Meldrum's acid* (2,2-dimethyl-1,3-dioxane-4,6-dione) (**5**) is a colorless crystalline solid which is produced from malonic acid and acetone in the presence of acetic anhydride and traces of sulfuric acid [19–22]. Some physical properties are listed in Table 1. Its chemistry was reviewed in several publications [23, 24]. Meldrum's acid is frequently used for the preparation of malonic acid monoesters **6** [25–27] and β-keto esters **7** by acylation and subsequent alcoholysis [28].

6 **5** **7**

3. Malonates

Physical Properties. The most important malonates are the dimethyl and the diethyl ester. Both are colorless liquids that are sparingly soluble in water (1 g/50 mL for diethyl malonate), but miscible in all portions with diethyl ether and ethanol. At room temperature, malonates ($pK_a \approx 13$) and alcoholic solutions thereof exist almost exclusively in the keto form.

Of the malonates derived from higher alcohols, only the diisopropylester is of industrial use. The physical properties of the most important malonates are shown in Table 1.

Chemical Properties [29]. Mono- and dialkylation of malonates with alkyl halides [30–33] or sulfonates [34, 35] are usually performed in the presence of alkoxides or with sodium hydride. Subsequent hydrolysis of one ester group and decarboxylation allows the introduction of the CH(H)–CO_2R (R = Me, Et) moiety into an organic molecule (*Malonic ester synthesis*). Similarly, acylation of malonates with acid chlorides [36] yields β-keto esters after hydrolysis and decarboxylation [37–39]. Reaction with aldehydes or ketones (Knoevenagel condensation) affords ylidene-malonates [40]. Reduction of dialkyl malonates with LiAl(O-*tert*-Bu)$_3$H proceeds with selective reduction of one of the ester groups to provide β-hydroxy esters in good yields [41]. Michael addition of malonates to mesityl oxide [*141-79-7*] gives 5,5-dimethyl-1,3-cyclohexanedione-4-carboxylic acid after ring closure. Subsequent decarboxylation leads to dimedone [*126-81-8*] (**8**) [42, 43]. Reaction of diethyl malonate with triethyl orthoformate affords diethyl (ethoxymethylene)malonate [*87-13-8*] (**9**) [44]. Mesoxalic acid diesters **10** can be obtained by metal-catalyzed air oxidation of malonates [45]. 2-(Acylamino)-malonates **11** are available by nitrosation of malonates followed by simultaneous acylation and hydrogenation [46–49]. Alkylation of **11**, followed by hydrolysis, and subsequent decarboxylation affords α-amino acids [50–52]. Dialkyl malonates can be used for the selective synthesis of monoalkyl malonates [53–55] and for the preparation of mixed malonates by transesterification [56, 57]. A two-step process for the preparation of Meldrum's acid (**5**) from diethyl malonate has been reported [58].

8

9

10

11

Finally, malonates and their 2-substituted derivatives can be converted into nitrogen heterocycles. Pyrazolones are obtained by reaction of malonates with hydrazines [59]. By condensation with urea or thiourea, 2,4,6-trihydroxypyrimidines or 2-thio-4,6-dihydroxypyrimidines are formed, and with guanidine 2-amino-4,6-dihydroxypyrimidines are obtained [60]. Similarly, 4,6-dihydroxypyrimidines are available from malonates and formamide [61–63] and 2-alkoxy-substituted-4,6-dihydroxypyrimidines by condensation of malonates with *O*-alkylisoureas [64, 65].

Production. Two processes have become established for the industrial production of malonates [66].

Hydrogen Cyanide Process. This process is based on hydrogen cyanide and chloroacetic acid; the intermediate cyanoacetic acid is simultaneously saponified and esterified in the presence of a large excess of mineral acid and alcohol (Figure 1).

A solution of sodium cyanide (ca. 25 %) in water is heated to 65 – 70 °C in a stainless steel reaction vessel. An aqueous solution of sodium chloroacetate is then added slowly with stirring; the temperature must not exceed 90 °C. Stirring is maintained at this temperature for an hour. Particular care must be taken to ensure that the hydrogen cyanide, which is formed continuously in small amounts, is trapped and neutralized. The solution of sodium cyanoacetate is concentrated by evaporation under vacuum and then transferred to a glass-lined reaction vessel for hydrolysis of the cyano group and esterification.

The alcohol and mineral acid (weight ratio 1:2 to 1:3) are introduced in such a manner that the temperature does not rise above 60 – 80 °C. For each mol of ester, ca. 1.2 mol of alcohol is added.

Hydrochloric acid, which is formed as byproduct from unreacted chloroacetic acid, is fed into an absorption column. After the addition of acid and alcohol is complete, the mixture is heated at reflux for 6 – 8 h, whereby the intermediate malonic acid ester monoamide is hydrolyzed to a dialkyl malonate. The pure ester is obtained from the mixture of crude esters by extraction with benzene, toluene, or xylene. The organic phase is washed with dilute sodium hydroxide to remove small amounts of the monoester. The diester is then separated from solvent by distillation at atmospheric pressure, and the malonic ester obtained by distillation under vacuum as a colorless liquid with a minimum assay of 99 % (gas chromatography). The aqueous phase contains considerable amounts of mineral acid and salts and must be treated before being fed to the waste treatment plant. The process is suitable for both the dimethyl and diethyl esters.

The yield based on sodium chloroacetate is 75 – 85 %. Various low molecular mass hydrocarbons, some of them partially chlorinated, are formed as byproducts. Although a relatively simple plant is sufficient for the reaction itself, a sizeable investment is required for treatment of the wastewater and exhaust gas.

Carbon Monoxide Process. According to this process, dimethyl, diethyl, and diisopropyl malonates are produced by a dicobalt octacarbonyl-catalyzed reaction of chloroacetates (methyl, ethyl, or isopropyl) with carbon monoxide in the presence of the appropriate alcohol [67–70]. In the case of diethyl malonate the reaction is conducted at around 100 °C and 18 bar at pH 5.7 (Fig. 2) [71]. Ethyl acetate is formed as a major byproduct. After completion of the reaction, sodium chloride and catalyst are separated. The alcohol and the low-boiling components are distilled off and the nonconverted chloroacetate recovered by distillation. The crude ethyl malonate obtained is purified by redistillation.

Figure 2. Flow-sheet for diethyl malonate production by the carbonylation process

Alternative methods for the production of malonates, which have not been used industrially are the palladium-catalyzed reaction of ketene [*463-51-4*] with carbon monoxide in the presence of an alkyl nitrite [72], the ozonization of diketene [73], and the alkoxycarbonylation of dichloromethane [74, 75].

Uses. Dimethyl and diethyl malonates are widely used for the production of vitamins, pharmaceuticals, agrochemicals, fragrances, and dyes (Fig. 3). The use of barbituric acid [*67-52-7*] for the synthesis of vitamin B_2 (riboflavin) [76] is not important any more, because the prevailing process is now based on fermentation. Whereas barbituric acid itself has no physiological effects, barbiturates (5,5-disubstituted barbituric acids) and thiobarbiturates are widely used as hypnotics (→ Hypnotics), antiepileptics (→ Antiepileptics, Chap. 2.5), or anesthetics (→ Anesthetics, General, Chap. 2.1).

The vasodilator naftidrofuryl [*31329-57-4*] is prepared by alkylation of diethyl malonate first with 2-tetrahydrofurfuryl chloride [*3003-84-7*] and then with 1-(chloromethyl)naphthalene [*86-52-2*] followed by hydrolysis, decarboxylation and introduction of the diethylaminoethyl moiety [77]. 2-Substituted malonates are used for the synthesis of the antiepileptic vigabatrin [*60643-86-9*], derived from diethyl malonate and 1,4-dichloro-2-butene [78], and the anti-inflammatory drugs phenylbutazone [*50-33-9*], obtained from ethyl 2-(*n*-butyl)malonate [*133-08-4*] and 1,2-diphenyl-hydrazine [*122-66-7*] [79], and carprofen [*53716-49-7*], synthesized by Michael addition of dimethyl methylmalonate [*609-02-9*] to 2-cyclohexene-1-one [*930-68-7*] followed by hydrolysis, subsequent decarboxylation and formation of the carbazole unit [80]. Reaction of (ethoxy-methylene)malonate (**9**) with arylamino derivatives gives access to (aminomethylene)malonates, which are further upgraded into a wide range of quinolone antibiotics such as nalidixic acid [*389-08-2*] [81, 82], oxolinic acid [*14698-29-4*] [83], ofloxacin [*82419-36-1*] (*X* = O, R = CH_3) [84], or rufloxacin [*101363-10-4*] (X = S, R = H) [85]. Finally, 2-(acetylamino)malonate **11** (R′ = CH_3) is used for the synthesis of the anti-inflammatory and antiulcer drug rebamipide [*90098-04-7*] [86].

In the agrochemical field, malonates are mainly used for the production of two classes of herbicides: the cyclohexanedione-type and the sulfonylurea herbicides. The synthesis of the

Figure 3. Important products derived from malonates

1,3-cyclohexanedione herbicides commences with a Michael addition of malonates to 1-substituted but-1-en-3-ones followed by ring closure and subsequent decarboxylation. Examples of such herbicides are sethoxydim [*74051-80-2*] [87] and tralkoxydim [*87820-88-0*] [88]. The other prominent class are the sulfonylurea herbicides, derived from 2-amino-4-chloro-6-methoxypyrimidine [*5734-64-5*] (**12**), for example chlorimuron-ethyl [*90982-32-4*] [89]. 2-Amino-4-chloro-6-methoxypyrimidine is prepared by condensation of malonates with guanidine followed by chlorination and displacement of one chlorine atom with methoxide [90–92].

Diisopropyl malonate is used for the synthesis of the fungicide isoprothiolane [*50512-35-1*] by reaction with carbon disulfide and ethylene dichloride [*107-06-2*] [93] and for the hepatic protectant malotilate [*59937-28-9*] [94, 95].

Malonates and barbituric acid are also used for the synthesis of dyes such as C. I. Pigment Yellow 139 [*36888-99-0*], C. I. Pigment Yellow 150 [*25157-64-6*], and C. I. Disperse Yellow 5 [*6439-53-8*]. Dihydrojasmonate [*24851-98-7*], which is synthesized by Michael addition of a malonate to 2-pentyl-2-cyclopenten-1-one [*25564-22-1*] [96], is used in perfumery for blossom fragrances, in particular jasmine.

4. Cyanoacetic Acid and Cyanoacetates

Physical Properties. The physical properties of cyano-acetic acid and the most important cyanoacetates are listed in Table 2. Cyanoacetic acid forms colorless, hygroscopic crystals (*mp* 69 – 70 °C), that undergo decarboxylation above 160 °C to give acetonitrile. The compound has a dissociation constant of 3.65×10^{-3} in water (25 °C) and dissolves readily in water, but is only moderately soluble in ethanol, and sparingly in benzene. The industrially most important cyanoacetate is ethyl cyanoacetate, followed by the methyl ester. Both esters are colorless liquids, which are miscible with ethanol and diethyl ether but insoluble in water.

Chemical Properties. The chemical properties of cyanoacetates are quite similar to those of the malonates [97].

13 **14** **15**

Reaction with ammonia gives cyanoacetamide [*107-91-5*] (**1**) [98, 99]. Similarly, reaction of cyanoacetates with urea or its *N*-alkylated derivatives affords cyanocetylureas, which form pyrimidines upon ring closure [100, 101]. 2-Aminocyanoacetamide [*6719-21-7*] (**13**) is prepared by nitrosation of cyanoacetamide [102] or alkyl cyanoacetates [103, 104], followed by catalytic hydrogenation. Hydrogenation of cyanoacetic acid affords β-alanine (**14**) [105]. Cyanoacetates are also used as chain extenders. Thus, Knoevenagel condensation with aromatic aldehydes affords 3-substituted acrylonitriles after decarboxylation [106, 107], such as 3-thiophen-2-yl-acrylonitrile from thiophene-2-carbaldehyde [*98-03-3*] (**15**, Ar = thiophenyl) [108], 3-furan-2-yl-acrylonitrile from furfural [*98-01-1*] (**15**, Ar = furanyl) [109], or cinnamonitriles from benzaldehyde derivatives (**15**, Ar = phenyl) [110, 111]. With nonaromatic carbonyl compounds a shift of the double bond can occur to give β,γ-unsaturated nitriles [112, 113]. Finally, cyanoacetates can be converted into malonic acid monoesters or malonic acid monoamide monoesters [114] using microorganisms [115, 116].

Production. Cyanoacetic acid and the cyanoacetates are produced by the same route (and often in the same plant) as the malonates by cyanidation of sodium chloroacetate followed by acidification of the sodium cyanoacetate solution. Cyanoacetic acid is isolated by extraction with an organic solvent and evaporation of the solvent, whereas the cyanoacetates are obtained by mineral acid-catalyzed esterification with subsequent azeotropic removal of water [117–119]. Major byproducts are malonates and succinates. A process variation involves interchange of the cyanidation and esterification steps [120–122]. In this case, however, the formation of the side product dimethyl [*6283-71-2*] or diethyl [*10359-15-6*] 2-cyanosuccinate is difficult to suppress. In order to avoid the isolation, most of the cyanoacetic acid outlets are produced directly from solution.

Table 2. Properties of cyanoacetates and derivatives

Name	CAS registry no.	Molecular formula	Molecular mass	*bp*, °C	Density (20 °C), g/mol	Refractive index $(n)_D^{20}$	Flash point, °C*

* Pensky–Martens, closed cup DIN 51 758.

The world's largest cyanoacetate plant was brought on stream in 1987 in Mobile (Alabama) by Hüls. The annual production capacity of this plant was later expanded to 8000 t.

Alternative methods for the preparation of cyanoacetic acid involve the carboxylation of acetonitrile [123–125] and the oxidation of partially oxidized propionitriles [126–132]. Other methods for the preparation of cyanoacetates include the cleavage of cyanoacetaldehyde dimethyl acetal [133], formed by a palladium-catalyzed oxidation of acrylonitrile [134–137], the alkoxycarbonylation of chloroacetonitrile [138, 139] and pyrolysis of 3,3′-bisisoxazole in the presence of an alcohol [140]. However, none of these processes have been used industrially.

Higher Cyanoacetates. Large quantities of cyanoacetates of higher alcohols are usually obtained by esterification of cyanoacetic acid as described above [141], whereas smaller amounts are prepared by trans-esterification of methyl or ethyl cyanoacetate in the presence of aluminum [142] (e.g., aluminum isopropoxide), titanium [143] or tin catalysts [144, 145].

Uses. The most important application of cyanoacetates is in the field of adhesives. Knoevenagel reaction of alkyl cyanoacetates with formaldehyde affords α-cyanoacrylates **16**, which are stable under exclusion of air but polymerize rapidly to polycyanoacrylates **17** after application on a surface even at room temperature. This polymerization is reversible on heating and the monomer can be formed back and subsequently polymerized again by traces of moisture. Esters of higher alcohols (see Table 2), such as 1-butanol, are also employed.

16 **17**

Otherwise, cyanoacetates are used for the synthesis of pharmaceuticals, agrochemicals, dyes, and UV absorbers (Fig. 4). For many applications cyanoacetic acid, cyanoacetates, or cyanoacetamide (**1**) can be used alternatively. Caffeine (R = CH_3) [*58-08-2*] is synthesized from theophylline (R = H) [*58-55-9*], which is accessible in several steps from cyanoacetic acid and 1,3-dimethylurea [*96-31-1*] [146, 147]. The traded cyanoacetic acid is mainly used for the production of the fungicide cymoxanil [*57966-95-7*] [148, 149] and the cough remedy dextromethorphan [*125-71-3*] [150].

Ring closure of cyanoacetylurea [*1448-98-2*] affords 6-aminouracil [*873-83-6*] which is further upgraded into lumazine [*487-21-8*] (**18**) and the antihypertensive amiloride [*2609-46-3*] [151, 152] or into the antiinfective sulfadimethoxine [*122-11-2*] [153–155]. Reaction of cyanoacetates with guanidine affords 4-hydroxy-2,6-diaminopyrimidine [*56-06-4*] (**19**), which can be transformed into guanine [*73-40-5*] (**20**, R = OH) and 2-amino-6-chloropurine [*10310-21-1*] (**20**, R = Cl) [156–159]. Antivirals such as acyclovir [*59277-89-3*] (**21**, R^1 = OH, R^2 = $CH_2OC_2H_4OH$) [160, 161], ganciclovir [*82410-32-0*] (**21**, R^1

Figure 4. Important products derived from cyanoacetates

= OH, $R^2 = CH_2OCH(CH_2OH)_2$) [162], or famciclovir [*104227-87-4*] (**21**, R^1 = H, R^2 = $CH_2CH_2CH(CH_2OAc)_2$), [163] are significant outlets thereof. The synthesis of the antiepileptic ethosuximide [*77-67-8*] commences with a Knoevenagel condensation of a cyanoacetate with 2-butanone to give **22**. Cyanide addition, followed by hydrolysis, subsequent decarboxylation, and imide formation completes the synthesis [164, 165]. Other examples include the antiepileptic valproic acid [*99-66-1*] [166] and the uricosuric allopurinol [*315-30-0*], prepared from ethyl (2-ethoxymethylene)cyanoacetate [*94-05-3*] (**23**) and hydrazine [167]. Compound **23** is also a possible starting material for the preparation of the rice herbicide pyrazosulfuron-ethyl [*93697-74-6*] [168] and the fungicide fludioxonil [*131341-86-1*] [169]. Pyrazophos [*13457-18-6*] is another fungicide manufactured from cyanoacetate [170]. Reaction of ethyl cyanoacetate with sodium cyanide and paraformaldehyde affords ethyl 2,3-dicyanopropionate [*40497-11-8*] (**24**), which is further upgraded into the insecticide fipronil [*120068-37-3*] [171, 172]. The same building block might also be used for the preparation of the pesticide vaniliprole [*145767-97-1*] [173].

Reaction of cyanoacetamide (**1**) with bromine affords the biocide 2,2-dibromo-2-cyano-acetamide (DBNPA) [*10222-01-2*] [174]. Cyanoacetates are also used for the synthesis of dyes such as C.I. Disperse Yellow 31 (Celliton Fast Yellow 7G) [*4361-84-6*] [175]. Finally, the UV absorbers etocrylene (R = ethyl) [*5232-99-5*] and octocrylene (R = 2-ethylhexyl) [*6197-30-4*] are prepared by condensation of ethyl or 2-ethylhexyl cyanoacetate with benzophenone [*119-61-9*] [176] or benzophenone imine [*1013-88-3*] [177].

5. Malononitrile

Physical Properties. The physical properties of malononitrile are listed in Table 3. Malononitrile forms colorless crystals that are soluble in water, lower alcohols, diethyl ether, and acetonitrile, but insoluble in tetrachloromethane, petroleum ether, and xylene. After prolonged storage the crystals turn yellow to dark brown without significant degradation of quality.

* Abel-Pensky, closed cup DIN 51 755.

Chemical Properties. The chemical properties of malononitrile are determined by the nucleophilicity of the malononitrile anion, formed by deprotonation with relatively week bases and by the two electrophilic cyano groups [178–182]. Base-catalyzed dimerization of malononitrile affords 2-amino-1,1,3-tricyano-2-propene [*868-54-2*](**25**) [183, 184]. Reaction of malononitrile with trialkyl orthoformates gives (alkoxymethylene)-malononitriles (**26**, R^1 = OR, R^2 = H) which react with nucleophiles by displacement of the alcohol group. This reaction can be used for the synthesis of styryl dyes [185]. Dialkylation of malononitrile with alkyl halides [186] or acylation with acid chlorides and anhydrides is possible [187].

25

26

27

28

29

Knoevenagel condensation of malononitrile with aldehydes and ketones gives ylidene-malononitriles, which can undergo further reactions [188, 189]. Examples are the reaction with elemental sulfur (Gewald reaction) to give 3-cyano-2-amino-thiophenes [190, 191] or cy-

cloaddition reactions with azides to afford tetrazoles [192].

Bromomalononitrile [*1885-22-9*] (**27**, R^1 = Br, R^2 = H) is obtained in moderate yields by reaction of malononitrile with one equivalent of bromine [193]. With two equivalents of bromine dibromomalononitrile [*1885-23-0*] (**27**, $R^1 = R^2$ = Br) is obtained, which is usually isolated as a complex with potassium bromide. Thermal decomposition of this complex affords tetracyanoethylene [*670-54-2*] (**26**, $R^1 = R^2$ = CN) [194–198]. Reaction of dibromomalononitrile with potassium cyanide yields the potassium salt of tricyanomethane (**27**, R^1 = CN, R^2 = H) [199]. Alternatively, tricyanomethane is available from malononitrile and cyanogen chloride [200]. Tricyanomethane can be used for the synthesis of ionic liquids [201].

Reaction of malononitrile with carbon disulfide in the presence of base affords the disodium [*4885-93-2*] or dipotassium salt [*4777-48-4*] of (dimercaptomethylene) malononitrile (**26**, $R^1 = R^2 = S^-$) [202], which is used for the synthesis of antimicrobials [203, 204]. Dimethylation affords [bis(methylthio)methylene]malononitrile [*5147-80-8*] (**26**, $R^1 = R^2 = SCH_3$), a versatile building block for the preparation of heterocycles [205–208]. Cyanothioacetamide [*7357-70-2*] (**28**) is best prepared by reaction of malononitrile with hydrogen sulfide [209–211].

Among the most important building blocks derived from malononitrile are the imidates, which are prepared by acid-catalyzed reaction of one or both nitrile groups with alcohols [212, 213]. Diimidates are convenient starting materials for the synthesis of nitrogen heterocycles, such as 4,6-dimethoxypyrimidines or bis(oxazolines) **29** [214]. For example, 2-amino-4,6-dimethoxypyrimidine [*36315-01-2*] (**30**) is produced from dimethyl malonoimidate dihydrochloride [*71160-05-9*] (**31**) by ring closure with cyanamide [*420-04-2*] (see Fig. 7) [215]. The bis(oxazolines) **29** can alternatively be prepared directly from malononitrile by a Ritter-type reaction (→ Amines, Aliphatic) [216] or by using a catalyst [217]. Bis(oxazolines) derived from malononitrile (or derivatives thereof) and chiral aminoalcohols are efficient ligands in asymmetric transition metal catalyzed reactions [218].

2-Aminomalononitrile [*5181-05-5*] (**27**, $R^1 = NH_2$, R^2 = H) is obtained either by nitrosation of malononitrile followed by catalytic hydrogenation or by reduction of (phenylazo)malononitrile [*6017-21-6*] (**32**) (see Fig. 7) [219–221]. Reaction of aminomalononitrile with guanidine yields 2,4,5,6-tetraaminopyrimidine [*1004-74-6*] (**33**) [222]. 2,4,6-Triaminopyrimidine [*1004-38-2*] (**34**) is available by condensation of malononitrile with guanidine [223, 224], and 4-amino-5-cyano-pyrimidine [*16357-69-0*] by reaction of malononitrile with formamidine [225].

Production. Until the mid-1970s malononitrile was obtained by dehydration of cyanoacetamide [*107-91-5*] (**1**), with phosphorus pentachloride [226] or phosphorus oxychloride [227, 228] in a batch process (see Fig. 1). Nowadays, only Chinese producers use this process for the production of small amounts. But there are still some new patents being issued concerning this reaction [229–233]. By far the major part of malononitrile is manufactured by a continuous high-temperature process in which acetonitrile and cyanogen chloride are fed into a tube reactor above 700 °C (Fig. 5) [234, 235]. Almost complete conversion is attained in one pass. The reaction products are malononitrile, excess acetonitrile, hydrochloric acid, and traces of maleic, succinic, and fumaric acids. The products leaving the reactor are immediately quenched to 40 – 80 °C, and gaseous hydrogen chloride is simultaneously separated, fed into a scrubber, and recovered as dilute hydrochloric acid. Excess acetonitrile is removed by a combination of vacuum distillation and thin-film evaporation. The recovered acetonitrile contains very little hydrogen chloride and can be recycled.

Removal of maleic and fumaric acid from the crude malononitrile by fractional distillation is impractical because the boiling points of these acids and malononitrile differ only slightly. Therefore, the impurities are converted into high-boiling compounds in a conventional reactor by means of a Diels – Alder reaction. The byproducts are finally removed by two vacuum distillations. The yield of malononitrile is 66 % based on both cyanogen chloride and acetonitrile.

Figure 5. Process flow-sheet for the production of malononitrile

Lonza in Visp (Switzerland) brought the first industrial plant using this process on stream in 1973 (Fig. 6).

Alternative ways reported to prepare malononitrile include its direct formation from cyanoacetates [236] or malonates [237] by reaction with ammonia in the presence of a dehydrating catalyst; the molybdenum-catalyzed reaction of 3-hydroxypropionitrile [238] with ammonia and oxygen, vapor phase oxidation of 3-aminopropionitrile in the presence of ammonia [239], vapor phase reaction of allene with ammonia in the presence of oxygen [240], a high temperature reaction of dicyanogen with acetonitrile [241], and the thermal reaction of isonitriles with nitriles [242]. However none of these routes are used on an industrial scale.

Transportation. Malononitrile is shipped as solidified melt packed into 200-L lined drums or as a solution in methanol. Care should be exercised when remelting the solidified product, because spontaneous decomposition can occur when it is exposed for an extended time at elevated temperatures, particularly above 100 °C. A water bath is recommended for this purpose.

Uses. Malononitrile is extensively used as a building block for the synthesis of vitamins, agrochemicals, pharmaceuticals, and dyes (Fig. 7). The two most important outlets for malononitrile are thiamine (vitamin B_1) [*59-43-8*] [243, 244] and the sulfonylurea herbicides based on 2-amino-4,6-dimethoxypyrimidine [*36315-01-2*] (**30**), such as benzsulfuron-methyl [*83055-99-6*] [245], azimsulfuron [*120162-55-2*] [246], pyrazosulfuron-ethyl [*93697-74-6*] [168], or halosulfuron-methyl [*100784-20-1*] [247, 248]. Other outlets from malononitrile are the diuretic triamterene [*396-01-0*] [249, 250], the folic acid antagonist methotrexate [*59-05-2*] [251, 252], both prepared from 2,4,6-triaminopyrimidine [*1004-38-2*] (**34**), adenine [*73-24-5*] [253–256], the antihypertensive minoxidil [*38304-91-5*] [257, 258], and the pesticide dicyclanil [259, 260].

Furthermore, malononitrile is used for the synthesis of several yellow methine dyes with a *N*,*N*-dialkylaminoaryl group (aminoarylneutrocyanines) such as C. I. Disperse Yellow 90 [*6684-20-4*] (**35**, $R = CH_3$, $R^1 = C_2H_5$, $R^2 = C_2H_4OC(O)C_6H_5$) [261]. Blue aminoarylneutrocyanine dyes such as C. I. Disperse Blue 354 [*74239-96-6*] (**36**, $R=CH_3$, $R^1 = R^2 = C_6H_{13}$) are available by Knoevenagel condensation of 3-(dicyanomethylene)-2,3-dihydrobenzo[b]thiophene-1,1-dioxide [*74228-25-4*] with substituted benzaldehydes [262]. 1,4,5,8-Naphthalenetetracarboxylic acid [*128-97-2*] (**37**), used for the synthesis of perinone pigments, can be made by acylation of acenaphthene [*83-32-9*] with malononitrile followed by oxidation [263].

Charge-transfer salts of the malononitrile derivative 7,7,8,8-tetracyanoquinodimethane (TCNQ) [*1518-16-7*] are powerful electrical conductors [264]. TCNQ is made by condensation of malononitrile with 1,4-cyclohexanedione [*637-88-7*] followed by dehydrogenation [265]. Finally, condensation of *o*-chlorobenzaldehyde with malononitrile affords the tear gas (*o*-chlorobenzylidene)malononitrile [*2698-41-1*] (CS-gas) [266, 267].

Figure 6. Malononitrile plant of Lonza in Visp (Switzerland)

6. Quality Specifications and Analysis

Standard commercial quality of *malonic acid* has a minimum purity of 99 %. The analytical method usually applied for determination of purity is potentiometric titration with sodium hydroxide. Both equivalent points are measured, and the content is determined using the following equation:

$$\text{Content [\%]} = \frac{(E_2 - E_1) \times M \times 10.406}{W}$$

where E_1, E_2 are the volumes of standard sodium hydroxide solution at the first and second equivalence point, M is the molarity of the standard NaOH solution, and W the weight of the sample (in grams).

Malonate of standard commercial quality has a minimum purity of 99 % (gas chromatography).

Cyanoacetates are analyzed by gas chromatography, whereas potentiometric titration is used for cyanacetic acid. Standard commercial quality has a minimum assay of 99 %.

Malononitrile has a minimum purity of 99 wt % (measured by gas chromatography) and a solidification point of at least 30 °C.

7. Economic Aspects

The worldwide annual production capacity is believed to be more than 20 000 t for malonates, and more than 15 000 t for cyanoacetates. The production capacity has increased substantially over the past years, especially in the Eastern Hemisphere. A considerable overcapacity exists which has led to a price erosion. The most important products are dimethyl and diethyl malonate, methyl and ethyl cyanoacetate, cyanoacetic acid, and malononitrile. The ethyl esters are more important products than the methyl esters in both series. A large part of the cyanoacetic acid is used captively. The single most important producer for both cyanoacetates and malonates is Degussa–Hüls with plants in the USA and Europe (Table 4). The largest producer of malononitrile is Lonza in Switzerland. Worldwide production of malonic acid does not exceed a few hundred tons per year.

Figure 7. Reactions of malononitrile

Table 4. Estimated annual production capacity of cyanoacetates and malonates (t)

Country	Producer	Cyanoacetates	Malonates
United States	Degussa–Hüls	7000*	
Europe	Degussa–Hüls		7000*
Japan	Juzen, Tateyama	3000	4000
China		5000*	12 000
Korea	Samsung		2000
India		1000*	600

* Partly used for internal demand.

8. Toxicology and Occupational Health

Toxicology. Toxicological data of malonic acid and its derivatives are listed in Table 5.

Table 5. Toxicological data of malonic acid and important derivatives

Name	Skin irritation*	LD_{50}**, mg/kg
Malonic acid	mild	2750
Meldrum's acid	mild	> 5000
Dimethyl malonate	non-irritant	4520
Diethyl malonate	non-irritant	> 5000
Diisopropyl malonate	mild	> 5000
Diethyl methylmalonate	mild	> 5000
Cyanoacetic acid	mild	1500
Methyl cyanoacetate	mild	3062
Ethyl cyanoacetate	mild	2820
n-Propyl cyanoacetate	mild	> 5000
Isopropyl cyanoacetate	non-irritant	> 2000
Allyl cyanoacetate	non-irritant	160
n-Butyl cyanoacetate	mild	> 5000
2-Methoxyethyl cyanoacetate	non-irritant	4300
2-Ethoxyethyl cyanoacetate	mild	1250 – 5000
Malononitrile	mild irritant	14

* Rabbit,
** Oral, rat.

Occupational Health. Beyond normal safe handling measures no special precautions are necessary for the handling of *malonic acid*.

Dimethyl and diethyl malonate do not present any specific health hazards if handled with the usual precautions. Nevertheless, inhalation and skin contact should be avoided.

Because solid *cyanoacetic acid* and its solutions attack the skin, the acid should be handled carefully.

Because of the low LD_{50} (Table 5) and its chemical reactivity particular care should taken in handling *malononitrile*.

1. History [1], [2]

There is some dispute over the origin of the name "manganese". Deposits of manganese ore (probably pyrolusite) were apparently found near Magnesia in Asia Minor. This was referred to by PLINI around 50 B.C. as *magnesia negra* to distinguish it from *lapis magnes* (magnetite), which has a similar appearance and density. The name pyrolusite was derived only in 1826.

The useful properties of manganese were probably first identified in the mineral pyrolusite, which was used by the ancient Egyptians and Romans to control the color of glass. Small additions of the ore removed the greenish yellow discoloration caused by iron impurities, while further additions imparted pink, purple, or black colorations.

During the 1400s the name braunstein was used for all the manganese oxide ores. SCHEELE recognized manganese as an element in 1774, and GAHN succeeded in isolating the metal for the first time during the same year. The name manganese was first used by BUTTMAN in 1808.

Manganese ore may have been used in ironmaking for centuries, but found formal usage in iron- and steelmaking only at the beginning of the 19th century. Ferromanganese was first produced on an industrial scale in 1841 by POURCEL in France for use in crucible steels, and by 1850 spiegeleisen (an alloy of 20 % manganese and iron) had been produced commercially in Prussia. The Bessemer process was made practical by MUSHET, who advised the addition of spiegeleisen in 1856/1857. The use of ferromanganese as an additive to steel to counteract the harmful effects of sulfur and phosphorus was patented by SIEMENS in 1866, and by 1875, POURCEL was making 65 % ferromanganese in a blast furnace. HADFIELD developed a wear-resistant steel containing manganese as an alloying agent in 1888. Ferromanganese was first produced in an electric arc furnace during 1890.

A two-stage process for the production of refined ferromanganese with 1 – 2 % carbon was proposed in 1908, and manganese metal was first produced industrially by an aluminothermic process in 1898. In 1866 LECLANCHE filed a patent for the MnO_2-NH_4Cl-Zn dry-cell battery.

2. Properties [1–5]

2.1. Physical Properties

Manganese is a silver-grey metal, resembling iron. It is hard and very brittle, and its primary uses in a metallic form are as an alloying, desulfurizing, and deoxidizing agent for steel, cast iron, and nonferrous metals. Due to its high tendency to oxidize, annealing colors are often evident.

Figure 1. The vapor pressure of manganese [3]

Manganese belongs to group 7 and period 4 of the periodic table with an atomic number of 25 and atomic mass of 54.94. Six isotopes have been produced, of which only ^{55}Mn is stable. The other isotopes, ^{51}Mn, ^{52}Mn, ^{54}Mn, ^{56}Mn, and ^{57}Mn, have half-lifes ranging from 46 min to 310 d. Manganese exists in four allotropic forms: α, β, γ, and δ. Some important physical and thermodynamic properties are listed in Table 1. The vapor pressure of manganese in millibars is given by:

$$\log p = -13625/T + 8.8837 \ (770 - 885\,^\circ\mathrm{C})$$
$$\log p = -13994/T + 9.3360 \ (957 - 1097\,^\circ\mathrm{C})$$
$$\log p = -12275/T + 8.3730 \ (1250 - 1550\,^\circ\mathrm{C})$$

and the molar heat capacity in J mol^{-1} K^{-1} as a function of temperature by:

α-Mn (0.3 – 4.2 K):

$$C_p = [16\,T + 2.39\,T^{-2} + 0.0266\,T^{-3}]\cdot 10^{-3}$$

α-Mn (298 – 1000 K):

$C_p = 23.9 + 14.2 \cdot 10^{-3}\,T - 1.55 \cdot 10^5\,T^{-2}$
β-Mn (1000 – 1374 K):
$C_p = 34.9 + 2.765 \cdot 10^{-3}\,T$
γ-Mn (1374 – 1400 K): $C_p = 44.80$
δ-Mn (1410 K – *mp*): $C_p = 47.31$
Liquid Mn (*mp* – *bp*): $C_p = 46.06$

The vapor pressure diagram of manganese is shown in Figure 1.

2.2. Chemical Properties

Manganese exhibits certain similarities to its neighbors in the periodic table, iron and chromium. The electronic configuration is $1\,s^2\ 2\,s^2p^6\ 3\,s^2p^6d^5\ 4\,s^2$.

Manganese occurs in all oxidation states between Mn(−III) and Mn(VII), with Mn(II) being the most stable. Trivalent manganese is less stable and readily disproportionates into Mn(II) and Mn(IV). The remaining oxidation states occur mainly in complexes.

The basicity of the oxides decreases with increasing valency of the manganese. Thus, manganese(II) oxide is the anhydride of a base

$$Mn(OH)_2 \rightarrow MnO + H_2O$$

while manganese(VII) oxide Mn_2O_7 is an acid anhydride:

$$2\,HMnO_4 \rightarrow Mn_2O_7 + H_2O$$

Manganese(IV) oxide (MnO_2) is amphoteric. The oxidation states Mn(II) and Mn(VII) are of industrial importance, forming a large number of useful salts. In metallurgy, oxides of di-, tri-, and tetravalent manganese are important, especially Mn(II) oxide.

At normal temperatures, pure manganese is not attacked by oxygen, nitrogen, or hydrogen. At high temperatures it reacts violently with oxygen, sulfur, and phosphorus. It is therefore a powerful agent for deoxidizing and desulfurizing metals, whereby it is converted to a divalent oxide or sulfide. Reaction with chlorine forms manganese(II) chloride; with SO_2 the products are MnS and MnO.

Manganese dissolves in acids with liberation of hydrogen and formation of Mn(II) salts. Hot concentrated sulfuric acid dissolves manganese with evolution of SO_2, and nitric acid with evolution of hydrogen, nitrogen, and dinitrogen monoxide.

3. Occurrence [5–12]

Manganese is the twelfth most abundant element in the earth's crust, at 950 ppm [5].

Mineralogy. Manganese is contained in many minerals, of which approximately 250 can be regarded as true manganese minerals. The major ores, generally with manganese contents above 35 %, are hydrated or anhydrous oxides. The silicates and carbonates occur to a lesser extent. The major manganese minerals are listed in Table 2.

Economically significant manganese deposits are all of sedimentary origin, having been dissolved from crystalline rocks and deposited as the oxide, hydroxide, or carbonate.

Wad is the term given to the soft, earthy, hydrous mixture of manganese and iron oxides of variable manganese content.

Ore Quality. Typically, only ores containing a minimum of 35 % Mn are regarded as manganese ores. Ores containing 10 – 35 % Mn are categorized as ferruginous manganese ores, and iron ores with 5 – 10 % Mn are referred to as manganiferous ores.

The three most important areas of application of manganese ores and the specific requirements, are as follows:

1) Metallurgical grade ore for the iron and steel industry, which generally contains 38 – 55 % Mn. The phosphorus content should preferably be below 0.1 %, and the concentrations of Al_2O_3, SiO_2, CaO, MgO, and S are important. The manganese/iron ratio is critical; a 7.5 : 1 ratio, for example, is required for a standard ferromanganese alloy with 78 % Mn.
2) Battery grade ore, containing 70 – 85 % MnO_2 (44 – 54 % Mn). The ore should generally contain less than 0.05 % of metals more electronegative than zinc, such as copper, nickel, cobalt, and arsenic. The suitability of manganese dioxide for use in batteries depends on a number of factors, including the crystal structure, surface area, pore size distribution, particle shape and size, electrical conductivity, surface conditions, chemical composition, and structure defects [2].

Table 1. Properties of manganese

Property	α-Mn	β-Mn	γ-Mn	δ-Mn	Molten Mn
Atomic number	25				
Atomic mass	54.938				
Crystal structure	complex cubic	complex cubic	fcc	bcc	
Lattice parameter, nm	0.8894	0.6290	0.3774	0.3080	
Transition temperature, °C	$\alpha \leftrightarrow \beta$ 727	$\beta \leftrightarrow \gamma$ 1095	$\gamma \leftrightarrow \delta$ 1104	$\delta \leftrightarrow$ liquid 1244	liquid $\leftrightarrow$ gas 2032

Entropy, $J\,mol^{-1}\,K^{-1}$	32.0		32.3		173.8

Table 2. Manganese minerals of economic importance

Mineral	Formula	Theoretical Mn content, %	Relative density
Pyrolusite	β-MnO_2	63.2	5
Braunite	$Mn^{2+}Mn_6^{3+}SiO_{12}$	66.6	4.7 – 4.9
Manganite	γ-MnOOH	62	4.3
Psilomelane	$(Ba, Mn^{2+})_3$ $(O, OH)_6Mn_8O_{16}$	45 – 60	4.4 – 4.7
Cryptomelane	KMn_8O_{16}	62	4.3
Hausmannite	Mn_2MnO_4	73	4.7 – 5.0
Jacobsite	Fe_2MnO_4	23.8	4.8
Bixbyite	$(Mn, Fe)_2O_3$	30 – 40	5
Rhodonite	$(Mn, Fe, Ca)SiO_3$	42	3.4 – 3.6
Rhodochrosite	$MnCO_3$	47.6	3.3 – 3.6
Bementite	$Mn_3Si_2O_5(OH)_4$	43.2	3.5

3) Chemical grade ore whose specifications vary considerably depending on the end use. Included in this category are feed stocks for electrolytic manganese and manganese dioxide, manganese chemicals, colorants and, in the Republic of South Africa, an oxidant in uranium extraction.

Ore Deposits. The most important manganese ore deposits are located in the Republic of South Africa, the Soviet Union, Australia, Gabon in West Africa, and Brazil. The deposits in India and Mexico are of declining importance, and the majority of the production is consumed domestically.

The largest known land-based manganese deposit is the Kalahari Field, located in the Northern Cape Province of the Republic of South Africa, which contains ca. 78 % ($13\,600 \times 10^6$ t) of the world's potential resources. The surface area underlain by this deposit is approximately 320 km^2. The deposit is sedimentary and interlayered with banded ironstone.

A breakdown of the world's total estimated manganese ore reserves is presented in Table 3.

Table 3. Manganese reserves and production (1987)

	Ore reserves, 10^6 t [13]	Ore production, 10^3 t [14]	High-carbon ferromanganese production, 10^3 t [14]	Silicomanganese production, 10^3 t [14]
Ore-producing countries				
Republic of South Africa	13 600	2892	300 [a, b]	275
former Soviet Union	2300	9400 [a]	[c]	[c]

Each of the major manganese producers offers a range of ore products, the detailed chemical and physical characteristics of which are given in [8]. Analyses of some typical commercial grades are presented in Tables 4 and 5.

Another potentially important source of manganese are the deep-sea nodules located over certain areas of the ocean floor.

4. Mining and Beneficiation

The methods employed for the mining and beneficiation of manganese ore vary widely depending on the size and nature of the deposit, ore type, end uses, and size of the operation.

Mining. The major producers of manganese ore utilize both underground and open-cast mining techniques. In the Republic of South Africa, Samancor extracts ore from the open-cast Mamatwan Mine and the underground Wessels Mine. At Mamatwan the ore body attains a maximum thickness of 45.2 m and is overlain by, on average, 45 m of overburden. The open pit is approximately 1900 m by 300 m, and the ore is extracted from three benches by drilling, blasting, loading, and hauling to an in-pit crusher. At Wessels the ore body is located at a depth of ca. 300 m and a room and pillar mining system is employed. The average stope height is ca. 5 m,

Table 5. Typical compositions of some important battery grade manganese ores (chemical content on % dry basis)

CVRD, Brazil	76.5	51.0	3.2	0.035	0.050	0.080	0.004	0.035
Comilog, Gabon	83.6		1.8		0.03	0.05		0.095

and the ore is drilled, blasted, loaded, and hauled to underground primary crushing facilities.

At Groote Eylandt, BHP operates Australia's only manganese mine by open-cut methods from various quarries, each limited to an area ca. 250 m long by 60 m wide and normally having a single bench [15].

The former Soviet Union's primary manganese source is the Nikopol field, where the thickness of the ore seam is 1.5 – 2.5 m on average occurring at a depth of 100 – 120 m. A combination of underground and open-cut mining methods are employed [16].

Beneficiation. Ore treatment varies from simple crushing, washing, and sizing plants to fairly sophisticated beneficiation techniques. Gravity separation techniques are frequently employed, such as the dense-medium separation plants at Groote Eylandt and Mamatwan. Extensive investigations on a pilot-plant scale have been undertaken by Samancor on ore sorting techniques, based on neutron activation or X-ray fluorescence; this has not as yet led to a commercial operation. Froth flotation with fatty acids, amines, sulfates, sulfonates, and hydroxamates has been shown to be feasible on a laboratory scale [17], as have high-gradient magnetic separation techniques [18].

Beneficiation techniques are becoming progressively more complex as reserves of high-grade ores diminish and requirements for smelting and steelmaking become more stringent.

Intermediate treatment processes. Various intermediate treatment processes can be applied to manganese natural ores or concentrates prior to smelting to a ferroalloy or direct addition to a steelmaking process. These processes are employed for one or both of the following two reasons: 1) to convert a fine ore to a more suitable size, and 2) to calcine and/or reduce the ore to a more suitable final product.

Agglomeration processes include nodulizing, pelletizing, and briquetting. Reduction can be carried out in a rotary kiln or sinter plant.

Sintering has become the preferred process for intermediate treatment, and sintering grate areas varying from 3 m^2 to 80 m^2 and production capacities of 2 – 300 t/h.

Sinter is produced on a moving grate from a mixture of fine ore, fine reductant/fuel, and recycled sinter fines. The fuel in the bed is ignited, and ignition is propagated by applying suction to the grate. A sufficiently high temperature is generated to fuse the ore particles together. During sintering, the ore is calcined and partially reduced. Some of the benefits derived from sintering ore are:

1) Fine ore, which has a limited application and value in conventional smelting, is agglomerated and converted to a superior product.
2) Reduced gas volumes, and hence fewer furnace eruptions, result when smelting sinter.
3) Furnace availability and operating loads are increased.

5. Reduction of Manganese Oxides [19]

Manganese is only produced commercially from blends of ore in which manganese exists as an oxide. A knowledge of the thermodynamics of the reduction of these oxides is therefore essential to the understanding of the production of alloys from manganese ores.

5.1. Manganese – Oxygen System

Of the known oxides of manganese (Mn_2O_7, MnO_2, Mn_5O_8, Mn_2O_3, Mn_3O_4, and MnO), the only oxides found naturally in manganese ores are MnO_2, Mn_2O_3, Mn_3O_4, and MnO.

Under normal conditions, manganese dioxide occurs as stable β-MnO_2; the other modifications, α, γ, δ, and ε, are not pure varieties of MnO_2. Dimanganese trioxide (Mn_2O_3) exists in the α-modification, which is cubic above 20 °C and rhombic below this temperature; the γ-modification is metastable. Trimanganese tetroxide (Mn_3O_4) exists at atmospheric pressure in the tetragonal α-modification and changes to the cubic β-form at 1170 °C. Manganese oxide (MnO) in normal conditions exists in only one modification. This oxide is, however, nonstoichiometric and is more accurately described as $Mn_{1-x}O$, with $x = 0-0.25$ [20]. The complete phase diagram of the manganese – oxygen system above 1000 °C is given in Figure 2.

Figure 2. Mn – O phase diagram above 1000 °C [3]

The equations for the thermal dissociation of the important manganese oxides are as follows:

$$4\,MnO_2 \rightarrow 2\,Mn_2O_3 + O_2 \quad (1)$$
$$\Delta H_{298} = 166.0\,kJ$$
$$6\,Mn_2O_3 \rightarrow 4\,Mn_3O_4 + O_2 \quad (2)$$
$$\Delta H_{298} = 64.8\,kJ$$
$$2\,Mn_3O_4 \rightarrow 6\,MnO + O_2 \quad (3)$$
$$2\,MnO \rightarrow 2\,Mn + O_2 \quad (4)$$

The oxygen partial pressures exerted by these reactions are given as a function of temperature in Figure 3 [21]. According to the thermodynamic data in [22], the decomposition temperature at 101.3 kPa for reaction (1) is 500 °C and for reaction (2), 980 °C. For reaction (3) to occur at atmospheric pressure a reductant is necessary. Reaction (4) requires a high reducing potential. It is important, therefore, to consider the reduction of the oxides of manganese in the presence of carbon monoxide, hydrogen, and carbon. These are the reactions that usually take place in the blast furnaces and electric furnaces used to produce manganese alloys.

Figure 3. Variation of oxygen partial pressure in the Mn – O system with temperature

5.2. Reduction of Manganese Oxides with Carbon Monoxide, Hydrogen, and Carbon

The reduction of MnO_2 to Mn occurs in four main steps (see Eqs. 1 – 4). This reduction is strongly exothermic in the presence of carbon, methane, and carbon monoxide; the following equations apply:

$$MnO_2 + 1/4\,C \rightarrow 1/2\,Mn_2O_3 + 1/4\,CO_2 \quad (5)$$
$$\Delta H_{298} = -56.8\,kJ$$

$$MnO_2 + 1/8\,CH_4 \rightarrow 1/2\,Mn_2O_3 + 1/4\,H_2O + 1/8\,CO_2 \quad (6)$$
$$\Delta H_{298} = -58.6\,kJ$$

$$MnO_2 + 1/2\,H_2 \rightarrow 1/2\,Mn_2O_3 + 1/2\,H_2O \quad (7)$$
$$\Delta H_{298} = -79.5\,kJ$$

$$MnO_2 + 1/2\,CO \rightarrow 1/2\,Mn_2O_3 + 1/2\,CO_2 \quad (8)$$

$$\Delta H_{298} = -99.6\,\text{kJ}$$

The reduction of Mn_2O_3 in the presence of the same reducing agents is also exothermic. The following equations apply:

$$1/2\,Mn_2O_3 + 1/12\,C \rightarrow 1/3\,Mn_3O_4 + 1/12\,CO_2 \quad (9)$$

$$\Delta H_{298} = -16.3\,\text{kJ}$$

$$1/2\,Mn_2O_3 + 1/24\,CH_4 \rightarrow 1/3\,Mn_3O_4 + 1/24\,CO_2 + 1/12\,H_2O \quad (10)$$

$$\Delta H_{298} = -17.2\,\text{kJ}$$

$$1/2\,Mn_2O_3 + 1/6\,H_2 \rightarrow 1/3\,Mn_3O_4 + 1/6\,H_2O \quad (11)$$

$$\Delta H_{298} = -24.3\,\text{kJ}$$

$$1/2\,Mn_2O_3 + 1/6\,CO \rightarrow 1/3\,Mn_3O_4 + 1/6\,CO_2 \quad (12)$$

$$\Delta H_{298} = -31.0\,\text{kJ}$$

The third step is the reduction of Mn_3O_4, which is endothermic with carbon or methane and exothermic with hydrogen or carbon monoxide:

$$1/3\,Mn_3O_4 + 1/6\,C \rightarrow MnO + 1/6\,CO_2 \quad (13)$$

$$\Delta H_{298} = +11.8\,\text{kJ}$$

$$1/3\,Mn_3O_4 + 1/12\,CH_4 \rightarrow MnO + 1/12\,CO_2 + 1/6\,H_2O \quad (14)$$

$$\Delta H_{298} = +10.5\,\text{kJ}$$

$$1/3\,Mn_3O_4 + 1/3\,H_2 \rightarrow MnO + 1/3\,H_2O \quad (15)$$

$$\Delta H_{298} = -3.3\,\text{kJ}$$

$$1/3\,Mn_3O_4 + 1/3\,CO \rightarrow MnO + 1/3\,CO_2 \quad (16)$$

$$\Delta H_{298} = -17.2\,\text{kJ}$$

The last step, the reduction of MnO, is more difficult and requires a high reducing potential. The presence of carbon is therefore necessary, and at a carbon monoxide partial pressure of 101.3 kPa a temperature of 1420 °C is necessary for the reaction to proceed. However, the formation of manganese carbides in the presence of carbon lowers the reaction temperature to 1300 °C (see Section 6.3.1). The following, highly endothermic overall reaction applies:

$$MnO + C \rightarrow Mn + CO \quad (17)$$

$$\Delta H_{298} = 274.5\,\text{kJ}$$

This reaction can be broken down into

$$MnO + CO \rightarrow Mn + CO_2 \quad (18)$$

and the reaction of CO_2 with C to produce CO

$$CO_2 + C \rightarrow 2\,CO \quad (19)$$

which ensures that a high reducing potential is maintained.

Due to the importance of both carbon monoxide and carbon as reducing agents in the commercial production of manganese-containing alloys, these are discussed in more detail. It is possible to predict the ratio CO/CO_2 that will reduce the individual manganese oxides by considering the relationship between the oxygen partial pressures and the equilibrium constants for the reactions (1) – (4)

$$K_{p(1)-(4)} = p_{O_2} \quad (20)$$

(assuming that the activities of the solid phases are unity) and the equilibrium constant of the reaction

$$2\,CO + O_2 \rightarrow 2\,CO_2 \quad (21)$$

which is

$$\frac{1}{K_p} = \frac{p_{CO}^2 \cdot p_{O_2}}{p_{CO_2}^2} \quad (22)$$

and the relationships

$$G^0 = -RT \ln K_p \quad (23)$$

and

$$G^0 = -RT \ln p_{O_2} \quad (24)$$

the oxygen potentials of the individual reactions at various temperatures can be calculated. This is shown graphically in the Richardson diagram [21] (see Fig. 4). The same applies to the use of hydrogen as a reductant. Although the reduction of MnO_2, Mn_2O_3, and Mn_3O_4 takes place at low partial pressures of CO, the presence of carbon is necessary for the reduction of MnO. In this case the following reaction is important:

$$2\,C + O_2 \rightarrow 2\,CO \quad (25)$$

Figure 4. Temperature dependence and oxygen potentials of oxide systems [21]

for which

$$\log p_{O_2} = -\frac{11672}{T} - 9.16 \tag{26}$$

This reaction is pressure dependent due to the change in the number of moles of gas, and again the Richardson diagram can be used to predict under which conditions the reduction of MnO will occur (see Eqs. 17, 18, and 19). However, manganese carbides are always formed during the reduction of MnO with carbon, and this lowers the temperature at which the reaction occurs.

The products produced in this process always contain carbon. The phase diagram for the manganese – carbon system is shown in Figure 5. The melting point increases with increasing carbon content [23]. Commercial ferromanganese (76 % Mn, 16 % Fe) contains ca. 7 % carbon. The solubility of carbon decreases with increasing silicon content.

Figure 5. Phase diagram for the Mn – C system [23]

5.3. Reduction of Mixed Oxides and Minerals Containing Manganese Oxides

In the discussion of the reduction of manganese oxides it has been assumed that the activity of the solid phases is unity. However, this is usually not true in practice because in most manganese ores the manganese oxides are combined with iron oxides, silicates, aluminum oxides, calcium oxides, and phosphorus oxides.

The oxides FeO and P_2O_5 are reduced at lower temperature than MnO, and SiO_2 at only slightly higher temperature (see Fig. 4). Any iron oxides and oxides of phosphorus occurring in the ore, fluxes, and reductants used in commercial processes are reduced together with the manganese oxides and report to the product. A judicious choice of ores and raw materials is therefore necessary to limit the amount of these elements which report to the metal. The silica contained in the ores can also be reduced, and in the production of silicomanganese this is desirable. Quartz or quartzite is therefore an important raw material for the production of silicomanganese.

The presence of other oxides in the ores reduces the activity of the manganese oxide. This must be compensated for by increasing the reducing potential by increasing the CO/CO_2 ratio of the gas mixture. Alternatively, the reduction temperature must be increased if the reaction is carried out with carbon.

5.4. Reduction of Manganese Oxides by Silicon

Figure 4 shows that the reduction of manganese(II) oxide by silicon is also possible:

$$2\,MnO + Si \rightarrow SiO_2 + 2\,Mn \tag{27}$$

for which

$$K = \frac{a_{SiO_2} \cdot a_{Mn}^2}{a_{MnO}^2 \cdot a_{Si}} \tag{28}$$

This reaction is the basis of the Frisch process for the production of low-carbon ferromanganese and manganese metal from silicomanganese. The silicon content of the metal is restricted by using a basic slag that reduces the activity of SiO_2 by reaction with CaO, displacing reaction (27) as far to the right as possible.

5.5. Reduction of Manganese Oxide by Aluminum

It is easier to reduce manganese(II) oxide with aluminum than with silicon because the differences in the oxygen potentials of the dissociation equilibria of MnO and Al_2O_3 are greater than for MnO and SiO_2 (see Fig. 4). As in the case of carbon and silicon, the higher oxides of manganese are also reduced if present in the ore. The aluminothermic process is used in the production of manganese metal (see Section 7.3).

Table 6. Types of ferromanganese and their general compositions [26]

Alloy	Composition, %		
	Manganese	Carbon	Silicon
High-carbon ferromanganese (carburé)	72 – 80	7.5	< 1.25
Medium-carbon ferromanganese (affiné)	75 – 85	< 2.0	
Low-carbon ferromanganese (suraffiné)	76 – 92	0.5 – 0.75	
Silicomanganese	65 – 75	< 2.5	15 – 25
Ferromanganese silicon	58 – 72	0.08	23 – 35
Spiegeleisen	16 – 28	< 6.5	11 – 45

6. Production of Manganese-Containing Ferroalloys

A number of manganese-containing ferroalloys are manufactured which are used largely in the mild steel, foundry, and stainless steel industries [24–26]. The names and typical compositions of these alloys are given in Table 6, and the international standards for the most commonly used alloys, namely high-carbon ferromanganese HC FeMn and silicomanganese FeSiMn, are given in Table 7 [24]. These are generally classified as intermediate products and the range of their end uses is shown in Figure 6.

Generally, high-carbon ferromanganese and silicomanganese are produced from a blend of manganese-containing ores, and in the case of silicomanganese, slags and silica are added. Ferromanganese can be produced in either electric submerged furnaces or blast furnaces, although only four blast furnace producers exist in the Western world [25], whereas silicomanganese is largely produced in submerged arc furnaces. Producers of high-carbon ferromanganese and silicomanganese are listed in Table 8. High-carbon ferromanganese can be converted to medium-carbon manganese by an oxygen blowing process, and silicomanganese can be further refined into medium- or low-carbon ferromanganese as well as manganese metal (see Fig. 7).

6.1. Production of High-Carbon Ferromanganese

6.1.1. Production of Ferromanganese in Blast Furnaces [25–29]

Ferromanganese can be produced in blast furnaces in a manner similar to pig iron and spiegeleisen; however, in the Western world only four producers employ this method. These are Thyssen Stahl (Federal Republic of Germany), BSC Cleveland (United Kingdom), SFPO (France), and Mizushima (Japan) (see Table 10), [25]. In the former Soviet Union, the majority of the high-carbon ferromanganese is produced in blast furnaces [26]. The choice of the use of blast furnaces over electric furnaces is based on the relative price of coke and electricity. Blast furnaces are usually used where the cost of power is high in relation to coke. In blast furnaces, coke is used both as a reductant and as the energy source. The coke rate in blast furnaces is higher than in submerged arc furnaces, which use electricity as the power source [27]. An exception to this is SFPO, where off-gases from the furnace are used to produce electricity, which is sold back to the local power supplier.

The product produced from blast furnaces generally contains 76 % Mn and 16 % Fe; the ferromanganese produced in the former Soviet Union is generally of a lower grade (see Table 9) [26].

Raw Material Selection and Pretreatment. The raw materials required for the production of high-carbon ferromanganese are manganese ores, fluxes such as limestone, dolomite, or silica, and solid fuels and reductants such as coke.

In order to produce ferromanganese of the required grade a single ore is seldom suitable

Figure 6. Manganese intermediate products and end uses

Figure 7. Summary of process routes

Table 7. Ferromanganese standards [24]

Alloy	Country or organization	Standard	Reference

	former Soviet Union	GOST	4756-70
	Federal Republic of Germany	DIN	17 564

because the desired Mn/Fe ratio of the charge determines the Mn content of the final product [27]. Ores from various sources are therefore blended to achieve the ideal ratio and to limit the contents of the deleterious components silica, alumina, and phosphorus in the raw material mix.

The raw material is crushed and screened to ca. 5 – 30 mm. Alternatively, sintered or pelletized fine ore can be used (see Chap. 4). Some deleterious components can be partially removed from the ore prior to melting by dense-medium separation or flotation. Slagging components (dolomite or limestone) can be added to the sintered or pelletized ore, which results in cost savings in the blast furnace. Partial reduction of the higher manganese oxides may also occur during sintering.

Blast Furnace Operation. In comparison to iron making, high gas temperatures are required in ferromanganese production because the reduction of manganese(II) oxide takes place at a higher temperature than is required for the reduction of wustite [28]. This is achieved by oxygen enrichment of the hot blast or, in the case of SFPO, by heating the blast with nontransferred arc plasma torches [29]. The plasma arc increases the flame temperature from 2200 to 2800 °C and considerably reduces the coke consumption, which usually ranges from 1270 to 2000 kg/t.

The recovery of manganese in the alloy is usually 75 – 85 %. This is influenced by the MnO content of the slag, the slag-to-metal ratio, and losses in the flue gases. The MnO content of the slag is highly dependent on the basicity ratio $(CaO + MgO)/SiO_2$ (see Fig. 8) [30], which can be controlled by the choice of ore and addition of flux. Losses to the flue gas can generally be recovered in the gas cleaning section (see Section 6.5). These materials can then be agglomerated and returned to the furnace.

Figure 8. Variation of equilibrium MnO content of slag for high-carbon ferromanganese and silicomanganese production [30]
a) High-carbon ferromanganese (78 % Mn, 0.1 % Si, 7 % C, 14.9 % Fe); b) High-carbon ferromanganese (77 % Mn, 1.0 % Si, 7 % C, 15 % Fe); c) Silicomanganese (71 % Mn, 16 % Si, 1.8 % C, 10.2 % Fe)

At the Mizushima works, the double bell valve of the conventional blast furnace has been replaced with an arrangement incorporating a distribution chute (Fig. 9) [31]. This results in a better distribution of the burden in the shaft and therefore a more even flow of gas through the burden (see Fig. 10). The incorporation of a distribution chute lowers the coke consumption of the furnace.

In spite of the innovations mentioned above the raw material costs of blast furnaces remain higher than those of submerged arc furnaces [25]

∗ Furnace.

due to the high cost of coke. With the exception of SFPO, blast furnace production costs are higher than the average production cost of ferromanganese in electric furnaces.

The Reduction Process in the Blast Furnace. The reduction of the higher manganese oxides to manganese(II) oxide takes place in the upper zone of the shaft according to the reactions given in Section 5.2. These generally occur below 900 °C and are indirect. The reactions are exothermic, and the heat generated causes high top temperatures and necessitates water cooling of the furnace top.

The reduction of manganese(II) oxide

$$MnO + C \rightarrow Mn + CO$$

is highly endothermic, in contrast to the weakly endothermic reduction of wustite. This requires higher temperatures and, consequently, higher coke rates are required for the smelting of ferromanganese in blast furnaces.

6.1.2. Production of Ferromanganese in Electric Arc Furnaces

The majority of producers of ferromanganese in the Western world use submerged arc electric furnaces (see Table 10). Although electric furnaces have lower capacities than blast furnaces they have the advantage that the heat requirement is provided by electricity, and coke and coal are added to the feed only as reductants. Consequently the coke consumption is lower in electric furnaces than in blast furnaces, which is a considerable advantage in the light of dramatically increasing coke prices. An additional advantage is that the process is not entirely dependent on high-strength coke, unlike blast furnaces, and a portion of the carbon requirement can be supplied in the form of coal. In South Africa, where coking coal is in short supply, up to 70 % of the carbon for the production of ferro- and silicomanganese is supplied in the form of bituminous coal.

Originally electric furnaces were small (3 – 8 MVA); however, furnaces have grown progressively larger with time [32]. More recently built electric furnaces have capacities of 75 – 90 MVA. Smaller furnaces are still popular with producers because they offer flexibility in that they can be switched more easily between different products than their larger counterparts [33]. The larger size and more stable operation of modern electric furnaces, due largely to computer control, have resulted in lower electricity consumption. Electric furnaces used in the production of manganese alloys are generally cir-

cular and have three electrodes, each coupled to a separate electrical phase (see Fig. 11) [34]. The diameters of these furnaces range from 2 to 20 m.

In modern electric arc furnaces the raw material is usually fed by gravity from bunkers above the furnace. Fresh burden therefore automatically enters the furnace as the raw materials are melted and slag and metal are removed from the system. In older furnaces use is still made of charging cars to introduce raw materials to the top of the units.

Figure 10. Effect of mixing on the distribution of gas in a blast furnace [31]
A) For layer by layer charging; B) For perfect-mixed charginga) Cohesive zone; b) Lumpy zone; c) Raceway; d) Dead man; e) Throat sonde

As the raw materials move down the furnace, the higher oxides of manganese are reduced to MnO by the gas leaving the furnace. The reduction of manganese(II) oxide occurs by the contact of carbon with the molten oxide in the slag phase. The overall reaction is:

$$MnO + 10/7\,C \rightarrow 1/7\,Mn_7C_3 + CO$$

for which [35]

$$G^0 = 265.7 - 0.18T \text{ kJ}$$

The heat required for this endothermic reaction, for heating the burden, and to compensate for heat losses is supplied by the electrical input to the furnace. Heating takes place by the flow of electricity from the tips of the electrodes, which are submerged in the burden, through the burden and slag to the metal, as well as through the flow of electricity between the electrodes [35].

6.1.2.1. Design and Operation of Electric Furnaces

The degree of heating depends on the electrical current flow as well as the resistance provided by the burden and the slag to the flow of electricity. In the production of ferromanganese the resistivity of the burden is low, hence low voltages between the electrodes are necessary to maintain satisfactory penetration of the electrodes in the charge. The vapor pressure of manganese is high; therefore overheating of the charge must be avoided. The current densities on the electrodes should accordingly be lower for ferromanganese production than for other ferroalloys [36]. The diameters of the electrodes are therefore larger in ferromanganese furnaces than in other ferroalloy furnaces to facilitate the high currents required for low voltage operation. The distance between electrode centers is usually larger than in other furnaces, hence the furnace diameters tend to be greater. The values of these design

parameters for a number of operating furnaces are given in Table 11.

Most electric furnaces have two tapholes offset by 60 °C which are used alternately to tap both slag and metal. The slag and metal are then separated either in the ladle or by means of a skimmer plate in the runner between the furnace and the ladle [37]. In larger furnaces, separate tapholes are included for metal and slag [33]. Tapholes are usually opened by taphole drills and closed with automatic mud guns.

An important feature in the design of submerged arc furnaces is the Soederberg electrodes. These are used because the large electrode diameters required for the production of manganese alloys make the use of prebaked electrodes uneconomic. The Soederberg electrode consists of a mild steel or stainless steel casing which is stiffened with internal fins and is filled with a carbonaceous paste, consisting of a solid aggregate, usually calcined anthracite, and a binder of coal-tar pitch [33]. The paste becomes plastic when hot and fills the entire volume of the casing. On further heating of the electrode by the electric current and furnace heat, the paste is baked and becomes solid. As the electrode is consumed, additional casings are welded onto the top. The current carrying capacity and strength of an electrode is a function of the quality of the paste, the electrode baking rate, and the cross-sectional area. Breakages of Soederberg electrodes are a major cause of downtime in electric furnaces, and proper management of the electrodes is therefore essential for efficient production [33].

A number of devices are commercially available to control the electrodes' movement and slipping rate (rate at which the electrode is allowed to move through the rings to compensate for its consumption in the furnace). One of these is designed and manufactured by Elkem [37]. The electrode is clamped by hydraulically operated rings and is moved up and down on hydraulic cylinders. Current is fed to the electrode through brass contact shoes clamped around its diameter.

Large electric furnaces are usually completely closed at the top, and the CO-rich gas leaves the furnace at approximately 290 °C and is cleaned in cyclones and venturi scrubbers. The gas is then either flamed off to the atmosphere or, more recently, is used to generate electricity. This is the case of SFPO [25] and at Tinfos in Norway [38]. At Elkem's plant in Canada the off-gases are used to fuel auxiliary equipment in the plant [39]. Smaller furnaces are either open or closed. In the case of open furnaces the gas is usually withdrawn by fans and cleaned in a bag-filter plant. In this case the gases are completely burnt in the furnace and have no commercial value.

Raw materials are usually batch weighed and blended according to a predetermined recipe and are then fed to bunkers above the furnace. The mix then gravitates into the furnace through feed chutes. To ensure an even distribution of material over the furnace, up to ten feed chutes are radially distributed around each electrode and one is positioned in the center of the furnace.

After the metal is tapped from the furnace it is cast into molds formed from ferromanganese fines or cast iron and allowed to solidify. The alloy is then removed, crushed, and screened into various size fractions, depending on the requirements of the user. An alternative to this practice is the use of a casting machine. In this case the metal is tapped directly onto a moving train consisting of small molds. The metal then solidifies and is ejected from the mold at the end of the strand. The advantage of this process is that the product is more even in size and cubical in shape. The generation of fines (−6 mm), which are generally unsalable, is also minimized. To date Elkem, Samancor, Transalloys, Chuo Denki, and Mizushima use casting machines for a portion of their products.

6.1.2.2. Raw Materials Required for the Manufacture of High-Carbon Ferromanganese

Manganese ores from different sources vary widely in their contents of manganese, iron, silica, alumina, lime, magnesia, and phosphorus. To produce standard ferromanganese (78 % Mn) and a slag containing 30 % MnO, the manganese to iron ratio in the charge must be 6 : 5. Since a single manganese ore of this ratio is seldom available, blending of ores from different sources is common practice to reach the desired manganese to iron ratio and to control the level of deletereous elements, particularly phosphorus. The ore mixes used in some operations

are shown in Table 12, [36]. The use of sinter as a source of manganese is becoming increasingly popular. In the sintering process a degree of prereduction is achieved, reducing the energy requirement in the furnace. The additional advantage of sinter is that fine ores, which are otherwise unusable, are agglomerated in the sintering process. Bag-house dust and sludge from gas cleaning plants can also be recycled to the furnace in the form of sinter. The maximum amount of sinter that can be fed to the furnace is a moot point and depends on its mineralogy and state of prereduction. When sinter replaces ore of high MnO_2 content, the energy required in the furnace increases because the highly exothermic reduction of MnO_2, Mn_2O_3, and Mn_3O_4, (see Section 5.2) no longer takes place in the furnace [36]. The use of Mamatwan sinter, in place of Mamatwan ore, results in power savings because the calcination of the carbonates in Mamatwan ore is energy consuming [40]. At the Zestafori ferralloy works in the former Soviet Union, up to 100 % sinter is used in the furnaces [41]. The bottom size of ore is also important because close packing of the ore in the furnace must be avoided [36]. This can result in the formation of calcined bridges in the furnace, which disrupt the distribution of gas and can cause eruptions when the

gas entrained under a bridge is suddenly released on its collapse [33]. Generally ores larger than 6 mm are used in large furnaces. The addition of small amounts of − 6 mm material to small furnaces is possible. Generally, ore is screened prior to batch weighing of the furnace mix.

The carbon required in the furnace is generally added in the form of coke. The size of the reductant is important. Coke and coal of too small a size can also cause close packing as well as affecting the resistivity of the burden. To maintain electrode penetration at Elkem Sauda [42] coke nuts (10 – 20 mm) are used. This is a compromise between the resistivity and the necessity of maintaining a coke bed at the bottom of the furnace.

Limestone, dolomite, or silica are added to the process as fluxes to adjust the basicity of the slag. The amount and type of flux added depends on the blend of ores and whether a discard- or high-slag practice is used. At Elkem's operation in Beauharnois the use of alumina as a flux makes the operation of the furnace possible with 100 % Moanda ore from Comilog [43].

6.1.2.3. Chemistry of the Process

A dig out of a 75 MVA ferromanganese furnace at the Metalloys operation in the Republic of South Africa showed that nine distinct zones exist around each electrode (see Fig. 12) [44]. This study showed that material descends rapidly down the side of the electrode (a) into the semi-active zone (b), where prereduction of higher manganese oxides to MnO takes place. Thereafter, the material moves into the active zones of the furnace (e, f), where reactions take place between the manganese(II) oxide in the melt and the coke particles in the coke bed:

$$7\,MnO + 10\,C \rightarrow Mn_7C_3 + 7\,CO$$

Equilibrium between the slag and metal was thought to exist under each electrode, and further from the electrode, layers of unreacted ore and coke were found to be present (h). This suggests that heat is concentrated under each electrode. The path of electrical transfer was deduced to be from the electrode tip through the coke bed and into the alloy layer (g).

The efficient production of high-carbon ferromanganese therefore depends on the degree of reduction of MnO by carbon as well as the prereduction that occurs in the upper region of the furnace. The ratio of CO and CO_2 in the off-gas is important and can be used to monitor the condition of the furnace. The higher the CO_2 content of the off-gas, the higher is the energy efficiency of the process, because the reducing potential of the gas is being more fully utilized (see Fig. 13) [42], [44]. Good operation of the furnace is indicated by a $CO_2/(CO_2 + CO)$ ratio of 0.55. This ratio, as well as the MnO content of the slag, can be used to control the coke rate of the furnace. Undercoking of the furnace is indicated by high MnO content of the slag and a low CO_2 content in the off-gas [42].

A further influence on the MnO content of the slag is the basicity ratio $(CaO + MgO) : SiO_2$. Generally the addition of basic oxides increases the melting point of the slag. The hotter slag improves the reaction between the slag and the coke and, consequently, more MnO is reduced. Increasing the basicity of the slag thus decreases the residual MnO content (see Fig. 8). The MnO content of the slag is also reduced by increasing the penetration of the electrodes, which also increases the slag temperature. The target MnO content of the slag depends on whether a discard- or high-slag process is used.

6.1.2.4. Discard-Slag Practice

Discard slags generally have MnO contents of 8 – 12 %. Slag is produced by the silica and other basic oxides entrained in the ore. Manganese(II) oxide is entrained in the silicate network and is released by addition of CaO or MgO. By increasing the basicity of the slag the recovery of manganese as metal is increased; however, consumption of carbon and electricity also increases. The discard-slag process is therefore only used where power is relatively cheap and the delivered cost of manganese ore is high [36]. The recovery of manganese to the metal is between 70 and 75 % when this practice is used. The practice usually involves the addition of limestone or dolomite to the furnace. However, in the Republic of South Africa where high proportions of Mamatwan ore are used, a basic slag is produced without the addition of limestone, due to the high CaO content of the ore. In India

Figure 12. Zones in a ferromanganese furnace [35]
a) Loosely sintered burden; b) Loosely sintered material enriched in carbonaceous reducing agents; c) Coke and slag region, showing the active zone away from the electrode; d) Coke bed; e) Coke-enriched layer, with $CaO-MnO-SiO_2$ slag; f) MnO melt layer with some slag, coke, and additional carbonaceous reducing agent; g) Ferromanganese alloy layer intermixed with MnO melt; h) Graphitized and carbon-rich material; i) Carbon lining; j) Brick lining; k) Slag taphole level; l) Metal taphole level; m) Pieces of electrode

the discard-slag practice is used because high recoveries of manganese are necessary to produce 74 % Mn from lower grade ores.

Figure 13. Relationship between off-gas composition and power consumption for ferromanganese production [42]

6.1.2.5. High-Slag Practice

In the high-slag practice less coke is required for reduction and little or no basic fluxes are used because the MnO content of the slag satisfies the requirement for basic oxides. Slags of this nature tend to contain more than 25 % MnO. In the high MnO practice the power consumption is reduced because a higher proportion of the reduction occurs by the gases and less MnO is reduced by solid carbon. Maximum use is therefore made of the exothermic nature of the prereduction reactions. The recovery of manganese is low in the ferromanganese furnace, but the overall recovery of manganese is high because the slag is usually used for the production of silicomanganese [36].

An additional attraction of the high-slag process is that an artificial ore, with a manganese to iron ratio of up to 100:1, can be made from relatively low-grade ores. This artificial ore can then be used to produce the highest grade of ferromanganese without the need to purchase costly high-grade ores. An additional benefit is the extremely low phosphorus content of the slag, which hence lowers the phosphorus content of any mix in which it is used. In countries

having only ores with high phosphorus contents, the first stage of the process is the production of a slag high in MnO and a low-manganese alloy [45].

Since the energy input in the production of ferromanganese by the high-slag process is lower than that of the discard-slag process, it is used by most producers. Slag compositions for various producers are shown in Table 12.

6.2. Production of Silicomanganese

Unlike ferromanganese, silicomanganese is only produced in electric arc furnaces, most of which can be used interchangeably to produce either of the manganese-containing alloys. Silicomanganese is used either as a substitute for ferromanganese and ferrosilicon in steelmaking or as a raw material for the production of medium- and low-carbon ferromanganese and industrial manganese metal. The composition of silicomanganese produced in the Western world is given in Table 6 and of that produced in the former Soviet Union in Table 13. Although silicomanganese generally contains 14 – 19 % Si, grades containing up to 35 % are produced for the production of extremely low-carbon alloys.

The solubility of carbon in the alloy decreases with increasing silicon content (Fig. 14) [46]. On cooling, sparingly soluble SiC comes out of solution.

Figure 14. Carbon solubility in the Fe – Mn – Si – C system (50 – 80 % Mn) at 1420 °C [46]

There are three general routes for the production of silicomanganese:

1) Reduction of manganese ores and silica with coke and coal
2) Reduction of MnO-rich slags from ferromanganese production and quartzite with coke and coal
3) Reaction of standard ferromanganese and quartzite with coke

The first two processes are used for the production of alloys containing 15 – 25 % Si and can be carried out in the same furnaces used for ferromanganese production. The third method is used to produce alloys containing 30 – 35 % Si and is generally performed in smaller furnaces.

Raw Materials. The raw materials used in silicomanganese production are similar to those used in making ferromanganese. Silica is added to the furnace as quartz or quartzite, and ferromanganese slag can be used as an alternative additional source of manganese instead of manganese ore or sinter. As in the case of ferromanganese, production advantages can be gained by using sintered ore (particularly from Mamatwan). At the Kashima works of Chuo Denki, 40 % of the ore feed is in the form of sinter. The raw materials used to produce silicomanganese are given in Table 14.

Chemistry of the Process. In a dig out of a small electric arc furnace [47], four zones were distinguished: the burden zone, the zone of the coke bed, the melting zone, and the metal layer. In the burden zone, the higher oxides of manganese are reduced to MnO, while the higher oxides of iron are reduced to FeO and partially to metallic iron. Manganese(II) oxide is converted to complex silicates, which begin to melt at the bottom of the burden zone. Fine metallic particles exist in the coke bed zone, which are possibly caused by condensation of silicon and manganese in the hot areas under the electrodes. In the upper and lower parts of the melt zone, the reduction of manganese and silicon oxides occurs. The equilibrium is determined by the following reaction [30]:

$$SiO_2 + 2\,Mn \rightarrow Si + 2\,MnO$$

This equation is important in determining the silicon and manganese contents of the metal that

collects in the lowest part of the furnace and is influenced by the slag chemistry and the temperature of the process. Increasing the CaO content of the slag reduces the silicon content of the metal. The basicity requirement of the slag is therefore better supplied in the form of MgO. Higher temperatures tend to drive Si into the metal at the expense of Mn. Higher temperatures are therefore required in the production of silicomanganese than in the production of ferromanganese.

Silicomanganese is produced by most manufacturers of manganese alloys, and the slag and metal compositions and operating parameters of some producers are given in Table 14.

To produce manganese metal of 97 % Mn by the silicothermic method (see Section 7.4) a silicomanganese containing 28 % Si is required that is particularly low in phosphorus and iron. This

is made from a manganese slag produced from the partial reduction of manganese ore (see Section 6.1.2.5).

Operation of the Furnace. The operation of the furnace for silicomanganese production is similar to that of ferromanganese production. However, deeper penetration of the electrodes is necessary to provide the higher temperature required to drive the reduction of silicon [30]. The resistivity of the burden is therefore important, and the size and the activity of the reductant is critical for stable operation of the furnace.

6.3. Production of Medium-Carbon Ferromanganese

Medium-carbon ferromanganese contains 1 – 1.5 % carbon and has a manganese content of 75 – 85 % (see Table 6). Medium-carbon ferromanganese can be produced either by refining high-carbon ferromanganese with oxygen or by the silicothermic route, whereby the silicon in silicomanganese is used to reduce additional MnO added as ore or slag. The former process has considerable advantages [46] and is used by most producers. Elkem Metals in Norway and the United States use their patented manganese oxygen refining (MOR) process to refine high-carbon ferromanganese in plants having capacities of 5000 t/month and have closed their silicothermic plant in the United States. A similar facility was sold under license to the Torros plant of Minera Autlan in Mexico. Thyssen Stahl (Federal Republic of Germany) uses a similar process to produce medium-carbon ferromanganese from the high-carbon ferromanganese produced in their blast furnaces. Samancor (Republic of South Africa) and Usinor Sacilor (France) have patented a similar process, but have not yet built a plant [48].

Transalloys (Republic of South Africa) produces 20 000 t/a of medium-carbon ferromanganese by the silicothermic route and appears to be the only producer in the Western world to do so. In the former Soviet Union, medium- and low-carbon ferromanganese are produced silicothermically with manganese recoveries of 59 – 63 % [26].

The silicothermic and MOR processes are shown schematically in Figure 15.

6.3.1. Production of Medium-Carbon Ferromanganese by Oxygen Refining of High-Carbon Ferromanganese

In the MOR process patented by Union Carbide, high-carbon ferromanganese is decarburized in a similar manner to the steelmaking process in the basic oxygen furnace [46]. However, several distinctive differences are encountered in the case of ferromanganese:

1) A final temperature of 1750 °C compared to 1550 °C
2) Refractory attack is more severe
3) Difficult casting of the final alloy
4) The higher vapor pressure of manganese
5) The higher volume and temperature of the off-gas

In the MOR process, oxygen is blown into the molten high-carbon ferromanganese and the temperature is increased from its tapping value of 1300 to 1750 °C. The heat required is supplied by the oxidation of manganese to manganese(II) oxide and carbon to carbon monoxide. The need to increase the temperature is shown by the carbon – temperature relationship in Figure 16. In the early part of the blowing process, most of the oxygen is consumed by oxidation of manganese, and the temperature of the melt increases from 1300 to 1550 °C. Hereafter, carbon is rapidly oxidized and the temperature rises to 1650 °C. Above this temperature, the rate of carbon removal decreases and manganese is once again oxidized. The process is stopped at 1750 °C, which corresponds to a carbon content of 1.3 %. Further reductions in carbon content result in unacceptably high losses of manganese. In the MOR process, the recovery of manganese is ca. 80 % and the distribution of manganese can be broken down as follows [46]:

Alloy MC FeMn	80 %
Fume formed by vaporization	13 %
Slag formed by oxidation of Mn	5 %
Other losses, splashing	2 %

The manganese lost in the fume is recovered in the gas cleaning plant and is then pelletized and returned to the high-carbon ferromanganese furnace. The slag, which contains about 65 %

Figure 15. Process flow sheet comparison for silicothermic reduction and the MOR process [46]

MnO, is also returned to the high-carbon ferromanganese furnace. The successful operation of this process depends on the design of the blowing vessel and oxygen lance as well as giving careful attention to operational procedures. In the joint patent of Samancor and Usinor Sacilor, a bottom blown converter is used and steam is injected at the end of the blow as a coolant [48].

Figure 16. Dependence of carbon content on temperature for a ferromanganese alloy (Mn : Fe, 6 : 1) at 101.3 kPa [46]

The MOR process has many advantages over the silicothermic process: lower energy consumption, lower capital investment, lower production cost, and greater flexibility.

The main disadvantage of the process is that its use is limited to production of medium-carbon ferromanganese because the carbon content cannot be reduced to below 1.3 %.

6.3.2. Silicothermic Production of Medium-Carbon Ferromanganese

In the silicothermic production of medium-carbon ferromanganese, a high-grade slag or a melt containing manganese ore and lime is contacted with silicomanganese containing 16 – 30.1 % silicon [49]. The silicon in the alloy acts as the reducing agent in the process, which reduces the manganese(II) oxide in the melt. Similarly to silicomanganese production, the equilibrium is determined by the reaction:

$$Si + 2\,MnO \rightleftharpoons SiO_2 + 2\,Mn$$

The purpose of the lime is to reduce the activity of the SiO_2 in the melt, thus forcing the above reaction as far to the right as possible. The ratio of CaO to SiO_2 in the slag should be greater than 1.4 to ensure a sufficient reduction in the activity of SiO_2. The carbon entering the process in the silicomanganese remains entirely in the metal phase and is therefore found in the product. Thus, to produce a medium-carbon ferro-

manganese containing 1 % C, a silicomanganese containing 20 % Si is necessary (see Fig. 14).

The heat produced by the silicothermic reduction is not sufficient to sustain the process; hence it is usually carried out in an electric arc furnace. These furnaces are usually small and, unlike ferromanganese furnaces, are lined with magnesite bricks, which are fairly resistant to the highly basic slag. The power consumption is between 1000 and 3000 kW. These furnaces can be tilted so that the slag can be separated from the metal. At Transalloys (Republic of South Africa) the process is carried out in a mixing ladle.

Although the silicothermic reduction process is more energy intensive than the decarburization of high-carbon ferromanganese, it has the advantage that the final carbon content is limited only by the carbon content of the initial silicomanganese. The silicothermic process can therefore be used to produce low-carbon ferromanganese and industrial manganese metal (see Section 7.4).

6.4. Production of Low-Carbon Ferromanganese

Low-carbon ferromanganese contains 76 – 92 % Mn and 0.5 – 0.75 % C (see Table 6). The production of low-carbon silicomanganese is not possible by the decarburization of high-carbon ferromanganese without incurring extremely high losses of manganese [49]. Use must accordingly be made of a silicothermic reduction process.

The process is similar to that used in the silicothermic production of medium-carbon ferromanganese. High-purity ores are used and in particular ores containing iron and phosphorus should be avoided. An artificial manganese ore, produced as a high-grade slag (see Section 6.1.2.5) is particularly suitable because of its low impurity level and because all the manganese is present as MnO. The reduction of the higher oxides of manganese is therefore unnecessary.

The operating figures for 1 t of ferromanganese containing 85 – 92 % Mn, 0.1 % C, and 1 % Si with a manganese recovery of 75 % are:

Calcined manganese ore	1250 – 1350 kg
Silicomanganese (32 – 33 % Si)	800 – 850 kg
Quicklime	1000 – 1100 kg
Electrodes	10 – 12 kg
Electricity	1800 – 2500 kWh

Since the required silicon content of the metal is low, a slag high in MnO is necessary. The MnO content of the slag can, however, be reduced by the use of a two-stage refining operation. In the first stage, an excess of silicomanganese is maintained and a slag containing 6 – 8 % Mn is teemed and discarded. The second refining stage with manganese ore and lime results in a slag containing 10 – 14 % Mn, which is returned to the silicomanganese furnace.

6.5. Gas Cleaning

In all the processes described in this chapter, large volumes of gas are generated. These gases consist generally of CO, CO_2, and N_2, and contain large quantities of dust from the raw materials and condensed manganese droplets. These gases require cleaning prior to their venting to the atmosphere. In open furnaces, in which the gas is totally combusted, hoods are incorporated in the design through which the gas is removed. This gas is cooled in trombone coolers to ca. 200 °C and the dust is removed in bag filters. Ideally, after recovery the dust should be agglomerated and returned to the furnace. In closed furnaces, the gas is usually cleaned in cyclones and venturi scrubbers prior to combustion to the atmosphere or used in downstream processes. At Elkem Sauda in Norway, gas from the 36 MVA furnace is cleaned by two wet venturi scrubbers. The gas has an initial dust loading of 150 g/m^3 which is reduced to a maximum of 50 mg/m^3 [37]. The dust recovered from the cleaning plant is filtered, sintered and returned to the process. At Samancor's Meyerton works in South Africa the gas from the 81 MVA and two 75 MVA closed furnaces is cleaned by a cyclone followed by two venturi scrubbers. A mist eliminator is included in the gas plant of the 81 MVA furnace to reduce the moisture content because the gas is used for heating in other areas of the plant. The emissions from the gas plants are less than 50 mg/m^3, which is the statutory maximum. The gas from the remaining open furnaces is cleaned in a bag filter plant. Investigations are under way to briquette the dust from this plant

due to its high manganese content and high manganese to iron ratio.

It is expected that dust limits will be reduced to 25 mg/m^3. In addition to this the exposure limits allowed in the working environment in manganese producing facilities have been reduced due to the toxicity of manganese dust; the following limits apply:

United States, United Kingdom, Australia, Belgium, Brazil, Federal Republic of Germany	5 mg/m^3
Yugoslavia	2 mg/m^3
former Soviet Union, Poland	0.3 mg/m^3
Bulgaria	0.02 mg/m^3

6.6. Developments and Future Trends

Energy Saving Measures. In regions with high electricity prices developments have concentrated on the saving of energy. This is of particular importance to Japanese producers of manganese alloys that use electric furnaces. Developments include the use of the off-gas from the furnace to preheat and mildly prereduce the ore, either in a rotary kiln or in a shaft kiln above the furnace.

The former process is used at the Kashima Works of Chuo Denki, where the feed to the 40 MVA ferromanganese furnace is heated to 950 °C in a rotary kiln and the higher oxides of the manganese ore are partially reduced. The ore loses 23 % of its mass during this process [50]. The use of this system has resulted in savings in power, and an additional advantage is that coal can be used instead of coke to satisfy the carbon requirement of the furnace. Care must be taken to avoid rapid heating and consequent decrepitation of the ore in the kiln.

The process in which a shaft kiln is positioned above the furnace was invented by Nasu [51]. In this process the gas from the furnace is burnt under the furnace roof and the hot burnt gas leaves the furnace through a vertical shaft. The raw ore mix is introduced to the top of the shaft and is heated in a countercurrent fashion by the exhaust gas. The ore is then fed to the furnace, where further heating takes place as the ore is exposed to the radiant heat produced by the burning gas in the roof. Two furnaces of this type are in operation at the Mizushima plant and their operation has resulted in power savings.

Computer Control of Electric Furnaces. Computer control of electric furnaces is practiced by Elkem at Suada in Norway, at Marietta in Ohio, and at Beauharnois in Canada. Temco in Tasmania and Samancor in South Africa also use computer control [52]. The following improvements in operating parameters have been realized by computer control at Elkem's plant at Beauharnois:

Operating power level (MV)	5 % improvement
Power cost reduction from increased load	3 % improvement
Manpower cost reduction	9 % improvement
Statistical process control	lower variation in product

Elkem is investigating the potential of enhancing their process control system by the incorporation of an expert system. This system, based on artificial intelligence, will incorporate the experience of the operator in the process control system and will be used to diagnose reasons for poor furnace performance. Possible changes to improve the operation will be suggested by the expert system [53].

Use of Plasma Furnaces. Non-transferred arc plasma furnaces have been used successfully in the production of charge chrome. Attempts to produce ferromanganese in plasma furnaces have not been economically successful due to the high losses of manganese caused by volatilization in the arc attachment zone. In addition, no preheating of the ore takes place in a plasma furnace, unlike in the burden zone of the submerged arc furnace. In an effort to solve these problems and to utilize the higher specific throughputs that are obtainable in a plasma unit, a combined plasma/shaft furnace is being jointly developed by Voest Alpina and Samancor [54].

7. Production of Manganese Metal

[55], [56]

Pure manganese metal has only become an important commodity since ca. 1940. Today the world market is in excess of 140×10^3 t/a. Most

of the high-purity manganese produced is consumed by the steel and aluminum industries, although the use of manganese for the production of manganese – zinc soft ferrites has led to a demand by electronic component producers [57]. Whilst ferromanganese remains an economically sound additive for manganese steel producers, greater volumes of pure manganese metal are used in the formulation of specialty steels.

In aluminum production, manganese powder is added to the melt to make the product harder. Manganese powder has long been used in welding-rod fluxes, where it imparts superior flow properties to the melt forming the weld.

Producers of manganese chemicals enjoy the convenience of a pure, reactive starting material from which to manufacture manganese salts and compounds.

A number of methods for the production of relatively pure manganese metal are known:

1) Electrolysis of aqueous manganese salts
2) Electrothermal decomposition of manganese ores
3) Silicothermic reduction of manganese ores or slags
4) Aluminothermic reduction of manganese ores or slags
5) Distillation of ferromanganese
6) Electrolysis of fused salts

Techniques (1) and (2) are the most important; methods (3) – (6) are not of economic significance.

7.1. Electrolysis of Aqueous Manganese Salts

The electrolytic route to manganese metal was first investigated in 1930 by Davis. However, the process did not become significant until 1939 when demand for manganese by the steel producers (for armaments manufacture) prompted the U.S. Bureau of Mines to build a 1 t/a pilot plant at Knoxville, Tennessee. The plant was redesigned in 1940, and by 1944 it was producing ca. 1500 t/a. Chuo Denki Kogio of Japan commenced production in 1941. The U.S. Bureau of Mines built a second pilot plant at Boulder City in 1942 [58], and The Electrolytic Manganese Corporation of Krugersdorp, Republic of South Africa began production in 1955.

The Boulder City process forms the basis of modern electrolytic manganese plant operation and is encountered in many parts of the world. Production capacities according to country and company are listed in Table 15.

Table 15. Estimated production capacity for electrolytic manganese metal, 1988 [90]

Company	Country	Capacity, t
Fermavi Industria e Comercio	Brazil	80
Chuo Denki Kogio	Japan	3600
Tosoh	Japan	6000
Manganese Metal Company	RSA	43300
Elkem Metals	United States	10000
Kerr-McGee Chemicals	United States	11250
State organization	former Soviet Union	3000
Total		77230

The Manganese Metal Company of South Africa is currently the largest supplier but high prices in the late 1980s have encouraged investment by other countries.

The process may be conveniently divided into 3 stages:

1) Milling and chemical reduction of a suitable ore
2) Leaching of the soluble manganese and removal of deleterious solutes
3) Electrowinning of manganese metal

Ore Milling and Reduction. To ensure reactivity in both the reduction and leaching steps, the ore is milled to ca. 80 – 90 % $< 75\,\mu m$ [59]. The surface area (BET) is 2 – 5 m^2/g. It is usual to dry mill the ore since the hydrometallurgical part of the process is closed and unnecessary dilution of the liquor must be avoided. Ball or vertical spindle mills are suitable for this purpose. Transport of the ore may be effected pneumatically at this stage.

Manganese ores usually occur in an insoluble form comprising minerals largely in the 4 + oxidation state. Carbonate ores, which are readily soluble, occur in some parts of the world. To render refractory ores soluble in acid, the manganese is usually converted to the 2 + oxidation state by calcining under a reducing atmosphere at 850 – 1000 °C. Reductants are carbon sources

and may include various combinations of anthracite, coal, charcoal, hydrocarbon oils, natural gas, coal gas, or liquified petroleum gas. The reduction reactions can be simplified to:

$$CO + MnO_2 \rightarrow CO_2 + MnO$$

$$CO_2 + C \rightarrow 2\,CO$$

Other species present are also reduced. Iron is reduced to the iron(II) state and in some cases to iron metal. The Fe(II) content of the calcined ore may be used as an indicator of the degree of reduction achieved; a calcine containing 1 – 3 % Fe(II) can be assumed to have its manganese fully reduced to Mn(II).

The discharging calcined ore must be cooled to below 100 °C to exclude the possibility of reoxidation. The reactive nature of the calcine at this stage precludes pneumatic transport.

Reductive leaching has been investigated with bacteria [60] and with reducing chemicals such as sulfur dioxide, hydroquinone, and other organic compounds [61].

Leaching and Purification. The reduced ore is agitated with spent electrolyte which normally contains 2 – 5 % sulfuric acid (generated at the diaphragm in the electrolysis stage). Other soluble species, notably iron(II), are also dissolved and must be removed prior to electrolysis. The pH of the leachate should be 5 – 6, and air oxidation of Fe^{2+} to Fe^{3+} ensures the precipitation of iron(III) hydroxide to remove soluble iron [62]. Other deleterious transition metals are removed by precipitation of their sulfides through pH manipulation and addition of a soluble sulfide [63]. Some manganese sulfide is necessarily coprecipitated during this process and the relative amount of this present in the sulfide precipitate is a measure of the efficiency of the reaction [64–67]. The manganese concentration at this point is ca. 10 % expressed as the sulfate. If a substantial amount of soluble silica is present, it may be removed by coprecipitation with aluminum hydroxide. A solid – liquid separation is required to provide a perfectly clean solution for the electrolytic stage. Other methods of purification include ion exchange and solvent extraction [68], [69].

Electrowinning of Manganese Metal. Although manganese has a strongly electronegative electrode potential (– 1.13 V), its high hydrogen overvoltage allows electrowinning from aqueous solutions. Good current efficiencies are only obtained when other metallic solutes are absent from the catholyte.

The manganese is recovered in a diaphragm cell. The cathode may be made of titanium, stainless steel, or one of a number of proprietary alloys. The anode is usually a lead – calcium or lead – silver alloy, but success has recently been achieved with anodes coated with platinum-group metals. Diaphragms are usually made of synthetic polymer canvas.

Prior to introduction to the cell, the solution is conditioned by addition of sulfur dioxide or, more recently, selenium dioxide [70]. These additives improve current efficiencies and ensure the deposition of the hard and brittle α allotrope of manganese. It has been reported that the current efficiencies have been increased to as much as 90 % with selenium dioxide. However, the latter has the disadvantage that the metal obtained is often contaminated with selenium. This reduces the total manganese content of the metal and causes toxicological and environmental problems for the consumer. Addition of sulfur dioxide produces a metal with slightly higher sulfur content. Ammonium sulfate is used in the cell solution as a supporting electrolyte.

Typical cell operating conditions at the cathode are as follows:

$MnSO_4$ concentration	4.0 %
$(NH_4)_2SO_4$ concentration	13 %
pH	7.0
Temperature	35 – 45 °C
Current densities:	
Anode	1000 A/m^2
Cathode	500 A/m^2
Potential	5 – 7 V

These values are approximate and vary considerably between installations. Current efficiencies are variable, depending on additives, the purity of the catholyte, and optimization of solute concentrations. Values between 42 and 62 % are typical.

The following reactions occur [71]:
At the cathode

$$Mn^{2+} + 2\,e^- \rightarrow Mn^0$$
$$2\,H_2O + 2\,e^- \rightarrow H_2 + 2\,OH^-$$

At the diaphragm

$$(SO_4)^{2-} + 2\,H^+ \rightarrow H_2SO_4$$

At the anode

$$2\,H_2O \rightarrow 4\,H^+ + 4\,e^- + O_2$$
$$2\,e^- + Mn^{2+} + O_2 \rightarrow MnO_2$$

The electrolysis of water is largely responsible for the inefficiency of the electrolytic procedure. Power consumption is typically 9000–12 000 kWh/t. Polymeric smoothing agents may be added to the electrolyte to prevent the formation of dendrites and nodules on the cathodes, which usually cause the metal to be of inferior quality. Deposition time is dependent on current densities and varies between 12 and 30 h. Current efficiencies tail off rapidly as the thickness of the metal increases, and a compromise must be made between high efficiencies and the production of the thick metal flake required by the market. A thickness of 1.5–2.0 mm is considered optimum.

Metal Treatment. The cathodes are removed from the electrolysis bath after the appropriate deposition period. Since the α-manganese deposited is hard and brittle, it is readily stripped from the cathode starter-sheet by mechanical shock. The metal is then washed and dried. Absorbed hydrogen is removed by heating in air or under an inert atmosphere. The latter is necessary when manganese with a particularly low oxygen content is required. Metal destined to be milled must have hydrogen content $< 0.0005\,\%$ to minimize the explosion risk. A primary hydrogen explosion can initiate a secondary manganese dust explosion.

The metal is sold in flake, powder, or granular forms, depending on the end use. A generalization is that the steel industry requires thick flake, while the aluminum industry, welding-rod manufacturers, and manganese chemical producers require powders of various particle size distributions.

Other forms of manganese are also encountered; for example, powder and flake manganese which has had its surface passivated by mild oxidation. A market exists for briquettes of manganese and iron, or manganese and aluminum, which are conveniently added to melts of the appropriate metal to produce a particular alloy.

Quality Control and Analysis. Electrolytic manganese metal has a purity of $> 99.5\,\%$; no reliable method exists to determine manganese content directly. The sum of the impurities is therefore deducted from 100 % to obtain the assay of the metal.

A typical analysis (%) is:

Manganese	99.8
Oxygen	0.2
Nitrogen	0.005
Sulfur	0.02
Carbon	0.001
Iron	0.001
Copper	0.001
Cobalt	0.001
Nickel	0.001
Selenium	0.0005
Hydrogen	0.0006

When selenium dioxide is used as a cell solution additive, typical values (%) are:

Manganese	99.4
Sulfur	0.01
Selenium	0.3

Analytical methods described in this section are applicable to all types of manganese metal.

In large amounts, manganese is best determined by titration and many methods exist. The most reliable is the titration of the divalent ion with permanganate in a neutral pyrophosphate buffer that stabilizes the trivalent manganese species. A platinum redox indicator electrode is used with a suitable reference electrode. A microprocessor controlled automatic titrator facilitates precision and accuracy. The reaction can be summarized as:

$$4Mn^{2+} + MnO_4^- + 8\,H^+ + 15\,H_2P_2O_7$$
$$\rightarrow 5\,Mn(H_2P_2O_7)_3^{3+} + 4\,H_2O$$

The equivalence potential is ca. 0.47 V versus the saturated calomel electrode.

An alternative is to oxidize the manganese to permanganate with excess sodium bismuthate in the presence of nitric acid, add an excess of standard iron(II) solution and back-titrate with permanganate. This method has the advantage of not requiring sophisticated end-point detection equipment but suffers from a number of interferences. Variations on this oxidation/titration method include silver-catalyzed oxidation by persulfate followed by an arsenate titration [72].

Metallic impurities in both metal and process liquors are usually determined by absorption or emission spectroscopy, though various voltammetric techniques have been used to determine traces in pure metals. The half wave potential of manganese is − 1.57 V versus the saturated calomel electrode, making anodic stripping voltammetry ideally suitable for trace metal determination .

Nonmetallic impurities are universally determined by the use of commercially available equipment. The metal is usually heated above the melting point, in a gas stream, releasing the sought element in the form required. This is then determined in the gas phase by infrared absorption or thermal conductivity detectors. Nitrogen in greater than trace amounts has been determined by acid digestion, distillation, and colorimetric determination of ammonia (cf. Kjeldahl method for ammonia).

Summary. The electrolysis of aqueous solutions is the most important manufacturing route at present to high-purity manganese. Economic efficiencies are dependent on scrupulously clean solutions and strict control of operating parameters. The metal produced may be > 99.7 % pure and has many varied uses.

Manganese has also been produced by the electrolysis of aqueous solutions at a flowing mercury cathode. This process, which operates at high current efficiencies, can deliver the manganese in a variety of forms, and is less dependent on solution purities. High electrolysis temperatures, and the inconvenience of coping with toxic mercury are possible reasons why there are now no full-scale plants using this process.

7.2. Electrothermal Process

This practice is a refinement of the silicothermic reduction of manganese (see below). However, the purity of the product obtained from the electrothermal process is superior.

The production of bulk manganese by this method is a well protected secret and little information appears in the literature. It is essentially a multistage hot refining process based on the following principles. Manganese ore is smelted in an arc furnace with a limited amount of reductant. This preferentially reduces the iron to metal with a small amount of manganese to form a low-grade ferromanganese with a high phosphorus content. The slag is thus refined to a purified manganese starting material.

The slag is used to produce a high-silicon silicomanganese (> 30 % Si) to ensure a low carbon content. Other ingredients such as quartz, limestone, and coke must be selected carefully to ensure a low contamination level. Coke, in particular, may have to be produced from special low-phosphorus coals.

The liquid silicomanganese is treated in two steps, with a liquid basic slag made from the purified manganese starting material. The operation is carried out in a ladle or a shaking ladle.

Typical analyses of electrothermal manganese are given in Table 16. From these analyses it can be seen that electrothermic manganese is a relatively pure product that competes in some areas with electrolytic manganese. The sulfur content is particularly low. The aluminum industry is experimenting the use of these products as alternatives to electrolytic manganese.

7.3. Aluminothermic Process

This production route is based on the well known thermite reaction in which a reactive metal liberates a less reactive metal from its oxide with the evolution of heat. The reactions possible for manganese oxides are:

$$3/4\,MnO_2 + Al \rightarrow 3/4\,Mn + 1/2\,Al_2O_3$$

$$\Delta H = -447.2\ \text{kJ/mol Al}$$

$$1/2\,Mn_2O_3 + Al \rightarrow Mn + 1/2\,Al_2O_3$$

$$\Delta H = -357.1\ \text{kJ/mol Al}$$

$$3/8\,Mn_3O_4 + Al \rightarrow 9/8\,Mn + 1/2\,Al_2O_3$$

$$\Delta H = -316.5\ \text{kJ/mol Al}$$

$$3/2\,MnO + Al \rightarrow 3/2\,Mn + 1/2\,Al_2O_3$$

$$\Delta H = -259.6\ \text{kJ/mol Al}$$

A heat of reaction of between 272 and 314 kJ/mol aluminum is necessary to sustain the reaction and ensure that it is not explosive. Therefore, some ores may require modification of the relative proportions of the different manganese oxides prior to reaction. This is achieved

Table 16. Typical analyses of electrothermal manganese ∗

∗ Gimel is a registered trade mark of Pechiney Electrometallurgie

by calcination at ca. 1000 °C. Certain circumstances require reduction of the ore by calcining in a reducing atmosphere (see page 30).

Calcium oxide is added to the mix to improve the flow properties of the slag, ensuring good separation of slag and metal. Lime also decreases the amount of silica reporting to the metal phase.

The aluminothermic route to manganese production is attractive in that it requires simple technology which is well documented, and low capital investment. Its disadvantages are that aluminum is expensive, and the exhaust gases from the process carry manganese and aluminum dust into the atmosphere. Efficiencies of up to 87 % have been reported.

7.4. Silicothermic Process

The production of manganese by silicothermic reduction resembles that of low-carbon ferromanganese in electric arc furnaces of 1 – 3 MW power consumption [73], [74]. The raw material used is either low-iron manganese ore or a manganese slag concentrate. The silicon is in the form of a special silicomanganese with ca. 33 % Si and < 3 % Fe. It is made from a manganese slag concentrate or from pure ores. Reduction as complete as possible is ensured by the addition of lime, which forms a basic slag.

Many slag changes are carried out during the process, as in the silicothermic manufacture of low-carbon ferromanganese. The refined metal has the following typical percentage composition:

Manganese	93 – 97
Carbon	< 0.10
Silicon	1.5
Phosphorus	< 0.06

The system is moderately efficient and the manganese yield is 63 – 64 %, with slag losses accounting for the remainder.

7.5. Distillation of Ferromanganese

Pechiney has filed patents dealing with the vacuum distillation of ferromanganese at 1200 – 1350 °C. The process has not been used on a large-scale since the manganese produced is inferior to electrolytic manganese and the production costs are prohibitive.

7.6. Electrolysis of Fused Salts

Manganese has been produced on a laboratory scale by the electrolysis of fused salts. A system in which an untreated manganese ore is dissolved in a fused mixture of calcium and manganese fluorides and electrolyzed at 1150 – 1200 °C has been described [75]. The cell potential was 5.5 – 6.5 V and current density was 9 – 11 A/cm^2 at the anode, and 2 – 2.5 A/cm^2 at the cathode. Manganese purity in the range 80 – 99.3 % was obtained at current efficiencies of 53 – 65 %.

8. Manganese as an Alloying Component [24]

8.1. Manganese in the Iron and Steel Industry

More than 90 % of the manganese mined is used in the steel industry (see Fig. 6). In the production of normal mild steel, high-carbon ferromanganese and silicomanganese are used; however, in special low-carbon steels, medium-carbon ferromanganese, low-carbon ferromanganese or electrolytic manganese is used. A steel producer has to weigh up the additional costs of the refined manganese alloys against the extra time in the argon oxygen decarburization (AOD) process that would be necessitated by the use of carbon-containing alloys [50]. Manganese occupies a special place among all alloying elements as it is present in almost all types of steel and cast iron.

The addition of manganese to iron – carbon systems has the following effects:

1) It retards the rate of transformation (i.e., it increases the hardenability).
2) It lowers the martensitic start temperature. This effect is 40 °C at 1 % addition of manganese and increases linearly to 200 °C with 5 % addition.

Manganese has extensive solid solubility in austenitic iron; therefore, it has no solution hardening effect in austenite. The solubility of manganese in ferritic iron is limited to 3 %. Hence, manganese exhibits a solution hardening effect in ferrite (30 – 40 MPa per wt % Mn).

Hadfield's austenitic manganese steels (which were developed from 1882) contain 1 – 1.4 % carbon and 10 – 14 % manganese. When they are quenched from 1000 °C the normal hardening transformation temperature is suppressed by the manganese and the steel remains austenitic at room temperature. These steels are exceptionally tough, have high tensile strength, and are wear resistant due to work hardening. As a consequence, they are used extensively in the mining and earth moving industries.

Manganese is a milder deoxidant than silicon and aluminum. Manganese enhances the effectiveness of aluminum and silicon as deoxidizers of steel due to the formation of stable manganese silicates and aluminates.

The solubility of nitrogen in ferrite is increased by the presence of manganese. The solution hardening effect of manganese is considerable enhanced by nitrogen, which is valuable in high-temperature creep-resistant alloys. Both the yield and ultimate stress at elevated temperatures are increased by the presence of nitrogen in steel, and this effect is enhanced by the presence of manganese.

Nitrogen is a powerful austenizing agent in steels and can be used as a partial substitute for nickel in austenitic stainless steels. The solubility of nitrogen in stainless steels is increased by the addition of manganese, and this is the basis of the series 200 stainless steels.

Manganese has had a long association with the efforts of steel makers to remove sulfur and to minimize the harmful effects of residual sulfur in steel. In the absence of sufficient manganese, sulfur can concentrate in the interstitial liquid in the form of ferrous sulfide. This compound has a low melting point and can persist as a liquid down to low working temperatures. This can cause cracking (hot shortness) during steel rolling. Steel requires a manganese to sulfur ratio of 4 for adequate ductility in the hot working range (950 – 1150 °C). In practice, ratios of up to 20 are used.

One of the most significant properties of steel is its ability to harden with heat treatment. A number of alloying elements can influence the hardenability of steels but manganese has become virtually synonymous with hardenability due to its effectiveness, availability, and relatively low cost. Increasing the manganese content permits the use of lower heat treating temperatures for steel parts where the use of higher temperatures would result in deformation.

Shortages, notably during the Korean War, originally prompted the use of manganese as a replacement for some of nickel in austenitic stainless steels.

In the AISI 200 series, about half, and sometimes more, of the nickel in a more conventional 18/8 steel is replaced by a combination of manganese and nitrogen. AISI 201 is at present the flagship of the series. Type 205 should be receiving increasing attention.

During the depressed price of nickel at below $ 6/kg until late in 1987, the price of type 201 in the United States remained lower than that of

type 301 or 304, and thus type 201 continued to be produced and used in the face of the oversupply of nickel. There is a price advantage inherent in series 200, which could probably benefit from further research and development. For example, a type 20 X, which contains some copper in addition to manganese, has been proposed as a direct challenge to type 304.

Technical problems previously associated with some manganese-bearing stainless steels (refractory wear, nitrogen introduction, continuous casting, rolling) have been largely overcome.

Numerous proprietary steels, some covered by patents and trade names, have been developed. The feature of these steels is not so much the saving in nickel, but their high strength and austenite stability under stress at low temperatures. Also, their corrosion, wear, galling, and welding properties are enhanced to various degrees.

The new version of type 201, which has a maximum carbon content of 0.03 %, may have an advantage over standard type 301 in applications involving welding and subsequent exposure to intergranular or stress-corrosion environments. The composition of the various series 200 stainless steels is given in Table 17.

Table 17. Nominal compositions of manganese steels, %

	201 a	201 b	205	20 X
C	0.05	0.03	0.15	0.1
Mn	6.75	6.50	15.0	7.0
Ni	4.0	3.75	1.0	3.0
Cr	16.75	16.75	17.25	14.75
Si	0.5	0.3	0.3	0.3
N	0.15	0.25	0.35	0.08
Cu				2.5

High-manganese stainless steels (e.g., 22 % manganese, 13 % Cr, 5 % nickel) have been developed by Kobe Steel for use as structural material at 4 K. The magnetic permeability of these steels at that temperature is 1.001, with no deterioration even after cold-working. These developments will find increasingly wide applications in fusion reactors, magneto-hydrodynamic generators, electromagnetic thrusters, and magnetically levitated (Maglev) trains.

8.2. Manganese in Nonferrous Alloys

Manganese alloys with nonferrous metals are made with low-carbon manganese. The addition of manganese improves hot and cold strengths, resistance to corrosion, and formability. A number of manganese alloys with nonferrous metals have therefore been developed, but of these only the alloys with copper and aluminum have achieved importance.

In combination with magnesium and other alloying metals, manganese produces the desired modification and hardening of aluminum alloys, e.g., Duralumin.

The Ni – Cu – Mn alloys have high electrical resistivity. The manganese contents of the most important copper alloys are given in Table 18. The alloy Manganin is used on a large scale as an electrical resistance material as its resistivity varies only slightly at high operating temperatures.

8.3. Nitrogen-Containing Manganese Alloys

The following types of manganese are suitable for nitriding: manganese metal, electrolytic manganese, and refined ferromanganese. High-carbon manganese can take up only small amounts of nitrogen because of the manganese already combined as carbide.

The nitriding process is carried out in annealing furnaces (e.g., hood type) in an atmosphere of pure nitrogen. The manganese metal or ferromanganese is in the form of powder or small pieces and the temperature is 700 – 1100 °C. Ferromanganese absorbs between 4 and 6 % nitrogen; increased manganese content gives increased uptake of nitrogen.

According to a patent of the Gesellschaft für Elektrometallurgie mbH, Düsseldorf [76] the nitrogen uptake of ferromanganese is improved by mixing with other ferroalloys such as ferrovanadium or ferrochrome. The nitriding is carried out by heating ferromanganese in an annealing furnace for 8 h at 950 °C in a nitrogen atmosphere at 101 kPa. Results obtained for the nitriding of low-carbon ferromanganese and ferrovanadium both separately and as a mixture are given in Table 19.

Table 18. Composition of some manganese-containing copper alloys

Alloy	Mn, %	Cu, %	Ni, %	Zn, %	Pb, %	Al, %	Fe, %

Mn, %	90.9		83.2		40.3
V, %		80.2		71.3	35.6
N, %	0.03	0.013	7.7	11.0	11.1

Table 20. Nitrogen-containing manganese alloys

Alloy type	Composition, %				
	Mn	N	C, max	Si, max	P, max
Sintered	75 – 85	4 – 6	1	1.5	0.20
Melted	80 – 85	1.5 – 2.5	0.10 – 0.30	1.5	0.15

Ferromanganese may also be nitrided in a medium-frequency induction furnace [77]. The temperature of the fine grained ferromanganese (1 – 5 mm) is raised to ca. 1200 °C, i.e., a little below the melting point. On cooling the furnace under nitrogen pressure, a sintered block is obtained containing up to 7 % N. If the nitrided ferromanganese is heated above its melting point, decomposition of the manganese nitride takes place and a molten ferromanganese is obtained with 1.5 – 2.5 % nitrogen. This nitrogen is distributed very uniformly in the alloy so that its use as a steel additive gives very reproducible nitrogen contents (see Table 20).

Ammonia is also used for nitriding of manganese and ferromanganese [77]. In this case, low temperatures are used (600 – 700 °C) and the nitrogen contents achieved are 12 – 13 %. Ammonia also leads to decarburization; in the nitriding of a ferromanganese powder, the carbon content is reduced from 1 % to 0.1 %.

9. Processing of Manganese Nodules and Encrustations

The primary economic interest in manganese deposits on the ocean floor has never been for the manganese content, but rather for the associated valuable metals, including nickel, copper, and cobalt. There are, however, some indications that the manganese content is becoming more attractive in its own right.

The deep ocean resources of manganese nodules were first discovered during the British HMS Challenger expedition of 1872 – 1876. The commercial potential of these resources was recognized in 1958 as a result of work undertaken at the University of California.

9.1. Occurrence, Origin, and Composition [78–81]

Occurrence. Manganese nodules occur over most of the deep ocean floor, but are currently considered to have economic potential in one

primary and three subsidiary areas (see Fig. 17). The primary area is located in the northwestern equatorial Pacific (the Clarion – Clipperton zone), and the subsidiary areas are in the South Pacific, western equatorial Pacific, and the central Indian Ocean. All of the main areas of potentially economically viable manganese nodules occur on the abyssal seafloor.

Limited quantities of ore-grade nodules have been identified within the Exclusive Economic Zones (EEZ) of some of the western Pacific islands.

Manganese encrustations occur on oceanic seamounts, primarily in the Pacific ocean.

Origin. Manganese on the ocean floor originates from two primary sources: runoff from the continents and submarine volcanic activity. It is believed that plankton extract the manganese and associated metals from seawater and carry them to the ocean floor after death. The metals are liberated by organic decay processes into the pore water of the deep-sea muds, where, by a series of diagenetic reactions, they migrate to centers of nucleation within the uppermost sediments and precipitate to form manganese nodules. Encrustations are formed on exposed rocks.

Composition. The chemical composition of manganese nodules varies widely. Some 74 elements have been found to occur in manganese nodules and encrustations. The average chemical composition varies from ocean to ocean and with latitude, water depth, and mineralogy.

World averages of nodule composition are influenced by the disproportionately high number of stations located in the Pacific Clarion – Clipperton zone, in which the nodules average 25.4 % Mn, 6.66 % Fe, 1.27 % Ni, 1.02 % Co. Excluding these values from the world averages decreases the average nickel, copper, and manganese contents, increases the iron content, and has no effect on the cobalt content.

Principle metal contents, together with nodule concentration and depth, are listed in Table 21.

The top of a nodule is generally higher in Fe, Co, and Pb and lower in Cu, Ni, Mo, Zn, and Mn compared to the bottom. The nodule core is usually deficient in Fe, Co, and Pb.

Physical Characteristics. Manganese nodules generally exhibit five external shapes: spheroidal, ellipsoidal, discoidal, botryoidal, and flat faced. The surface textures, which may be smooth or granular, may vary on the opposite sides of the nodule. The size varies from 0.5 – 20 cm, with concretions larger than 20 cm generally assuming the form of slabs. The color is usually dark reddish brown to black. Some zonal pattern in nodule cross section, produced by variation in mineral content of the growth layers, is generally present. The porosity is relatively high and relative density low (2.1 – 3.1).

Water comprises about 45 – 50 wt % of nodules when removed from the ocean. Air drying removes about half of this water. Approximately 5 – 10 % water is contained within the crystal structure.

Table 21. Chemical composition of manganese nodules

Element	Mean content, %	Range, %
Mn	18.60	0.04 – 50.3
Fe	12.47	0.30 – 50.0
Ni	0.66	0.01 – 1.95
Cu	0.45	0.01 – 1.90
Co	0.27	0.01 – 2.23

Mineralogy. Nodules comprise a complex mixture of organic and colloidal matter, nucleus fragments, and crystallites of various minerals. The phases are fine grained, often metastable, poorly crystallized, and intimately intergrown.

Todorokite, birnessite, and vernadite are the predominant manganese oxide minerals, while various other MnO_2 modifications in the form of α-MnO_2, β-MnO_2, and γ-MnO_2 have also been reported.

Iron is present as oxide, oxyhydroxide, and hydrated oxide phases, the most commonly observed being ferroxyhite, goethite, and lepidocrocite.

The accessory minerals can be divided into the following three categories: sheet silicates and zeolites, clastic silicates, volcanic minerals, and biogenic minerals.

Known minerals of nickel, copper, or cobalt have not been identified; Cu, Mo, Ni, and Zn are associated almost entirely with the manganese mineral phase. Ba, Cd, Ca, Mg, Sb, Sr, and V are usually associated with manganese but are

Figure 17. Manganese nodule occurrence
Hatched: areas of high nodule concentration; crosshatched: areas of potential economic viability

also found in other phases. Pb and Ti are associated almost entirely with the Fe and Mn phases.

9.2. Legal Considerations and Nodule Recovery [78], [80], [82–85]

Legal Considerations. The Law of the Sea as pertaining to the exploitation of mineral resources is of major importance to the future viability and prospects of commercial venture.

During the early 1960s interest in deep-ocean mining increased and the Third UN Law of the Sea conference began in 1974. The current Convention was eventually adopted by this conference in 1982.

The United States, the Federal Republic of Germany, and United Kingdom voted against the convention because of objections to certain provisions related to deep-sea mining.

The most important of the above regimes as pertaining to manganese nodule exploitation are the EEZ, extending to 200 nautical miles from the coastal state shoreline, and the so-called Area, extending beyond this limit. The coastal state has sovereignty over the EEZ, but the sea floor outside these zones falls under the jurisdiction of an International Seabed Authority which will be responsible for all mineral deposits and even mine these deposits through its own organization. The Authority would also license independent mining organizations to exploit these deposits, but in doing so would impose a number of conditions which some national governments and mining consortia find unacceptable.

The 200 mile EEZ would put under coastal state jurisdiction most of the minerals of the continental margins and, in some areas, those of the deep-ocean floor.

The convention also limits the amount of nickel that can be produced outside the EEZ over the first 20 years of commercial production in order to protect the markets of land-based producers.

The United States, Federal Republic of Germany, France, the United Kingdom, the former Soviet Union, and Italy have passed national deep-seabed mining legislation which, in many instances, is in contradiction of the UN Convention.

Nodule Recovery. Research into nodule recovery has been conducted since the 1960s and the technical feasibility, to a large extent, has been established.

Three main systems have been investigated: the continuous line bucket, the autonomous shuttle, and hydraulic pumping with a suspended conduit or dredge pipe.

Techniques based on continuous hydraulic pumping systems are the most technically and economically viable.

9.3. Processing [79], [80], [86], [87]

The following processes for recovering the metals of value (Mn, Co, Ni, Cu) from nodules have been identified as being potentially feasible:

1) Gas reduction and ammoniacal leach
2) Cuprion ammoniacal leach
3) Elevated temperature and pressure H_2SO_4 leach
4) Reduction and HCl leach
5) Smelting and H_2SO_4 leach

The first three of the above options recover Co, Ni, and Cu, while Mn can be optionally recovered from the tailings. The last two are more suited to the recovery of all four metals.

Ammoniacal processes are similar to those used for the treatment of land-based nickeliferous laterites which, in some respects, are similar to manganese nodules. Cobalt, nickel, and copper are soluble in $NH_3-(NH_4)_2CO_3$ (the Caron process) and $NH_3-(NH_4)_2SO_4$ solutions.

These processes involve selective reduction of the metals and disruption of the nodule matrix to permit rapid, complete dissolution of the valuable metals. Acidic chloride solutions are also capable of dissolving the valuable metals including manganese. Acidic sulfate solutions can solubilize cobalt, nickel and copper. Nickel is recovered from laterites by sulfuric acid leaching at elevated temperature.

The diverse chemical, physical and mineralogical composition of the nodules exclude physical enrichment prior to the complex hydrometallurgical processing. Separation on the basis of density, magnetic properties, or flotation has not been successful.

The recovery of manganese from the tailings of the ammoniacal processes (routes 1 and 2 above) involves flotation of the $MnCO_3$, which could then be converted to a manganese oxide product for further processing or sale. Manganese dioxide could be recovered from the H_2SO_4 process tailings (route 3 above) by dissolution and chemical the tailings from all the processes above for ferromanganese production is probably precluded due to the unacceptably high levels of trace metals, sulfur, and phosphorus.

9.3.1. Gas Reduction and Ammoniacal Leach Process

This process (Fig. 18) is an adaptation of the Caron process for nickeliferous laterites (see → Nickel).

The MnO_2 is reduced to MnO at 625 °C by a producer gas rich in CO. The mineral structure is disrupted by this reduction and the contained metals can be dissolved by an aqueous solution of 10 % ammonia and 5 % CO_2 at 40 °C and atmospheric pressure. The pregnant solution is separated from the solids, and copper and nickel are isolated by solvent extraction and aqueous stripping. The products are recovered as cathode copper and nickel by electrowinning.

The aqueous NH_3-CO_2 solution is contacted with hydrogen sulfide, and insoluble cobalt sulfides and residual copper, nickel, zinc, and other metals are precipitated.

This precipitate is removed and contacted with air and H_2SO_4 to selectively redissolve the cobalt and the small amount of nickel still present. The cobalt and nickel are recovered from the liquid in powder form by selective reduction with hydrogen at 3.4 MPa and 185 °C.

The residual ammonia and carbon dioxide are removed from the nodule residue by steam at 120 °C and 0.2 MPa. The resulting mixture is condensed and, together with the mixture of ammonia carbon dioxide and steam arising from the cobalt extraction step, is recycled.

9.3.2. Cuprion Ammoniacal Leach Process

Manganese dioxide is reduced in an aqueous ammoniacal solution containing an excess of copper(I) ions at 50 °C. The cobalt, nickel, and copper are solubilized in an aqueous solution of ammonia and carbon dioxide at 50 °C and atmospheric pressure. The separation and purification of the metals is identical to the Caron gas reduction process (see Section 9.3.1 and Fig. 18).

9.3.3. Elevated Temperature and Pressure H_2SO_4 Leach Process

In this process (Fig. 19) the cobalt, nickel, and copper content of the milled nodules is dissolved

Figure 18. Gas reduction and ammoniacal leach process

in a 30 % sulfuric acid solution at 245 °C and 3.54 MPa. Manganese and iron are not solubilized to any appreciable extent. The resultant slurry is cooled and the acid solution separated from the nodule residue. The residue is washed, neutralized, and disposed of. The pregnant solution is pH adjusted and the copper and nickel are selectively removed by extraction with an organic solvent. These metals are then stripped as copper and nickel sulfate in acidic aqueous solutions and subsequently recovered by electrowinning.

The cobalt is precipitated with hydrogen sulfide together with residual nickel, copper, and zinc. The precipitate is separated from the solution and contacted with air and H_2SO_4 at 100 °C to selectively redissolve the cobalt and residual nickel, which are recovered as powders from the solution by reduction with hydrogen gas at 3.4 MPa and 185 °C.

The ammonia is recovered from the barren solution and recycled. The barren, ammonia-free solution is recycled for washing of the leached nodule material.

9.3.4. Reduction and HCl Leach Process

In this process (Fig. 20) the manganese dioxide is reduced to soluble manganese chloride with hydrogen chloride at 500 °C and 0.1 MPa. A portion of the hydrogen chloride is oxidized to chlorine. The excess hydrogen chloride is separated from this chlorine and water vapor and recycled. Dissolution of the iron in the nodules is minimized by injection of steam, which results in the hydrolysis of iron chloride to insoluble ferric hydroxide.

The soluble Co, Ni, Cu, and Mn chlorides are dissolved by leaching with HCl. Copper is selectively extracted by organic ion exchange and subsequently stripped into a strong H_2SO_4 solution. The copper is recovered by electrowinning.

The copper-free chloride solution is neutralized and cobalt is removed by a second selective solvent extraction stage. The cobalt is recovered as a powder by a sequence of stripping, precipitation as cobalt sulfide by hydrogen sulfide, selective leaching, and hydrogen reduction.

Figure 19. High-temperature, high-pressure sulfuric acid leach process

Figure 20. Reduction and hydrochloric acid leach process

The copper- and cobalt-free solution is subjected to a third solvent extraction stage to remove nickel. The nickel is stripped into an acidic sulfate solution for subsequent electrowinning.

The final aqueous chloride solution can be dried to produce impure manganese chloride, which can be charged to an electrolysis furnace where it dissolves in a molten alkali chloride bath. Molten manganese is tapped from the furnace and cast. Chlorine gas is also produced from the electrolysis furnace and, together with the chlorine resulting from the initial hydrochlorination stage, can be converted to hydrogen chloride for recycling.

9.3.5. Smelting and H_2SO_4 Leach Process

In the sulfuric acid leach process (Fig. 21), the nodules are dried and the manganese dioxide and ferric oxide reduced to manganous and ferrous oxides at 625 – 1000 °C with coal and carbon-monoxide-rich producer gas. The reduced nodules, together with coke and silica, are hot-charged to an electric furnace.

In this step most of the Cu, Ni, Co, and Fe, and some of the Mn is reduced at 1425 °C to form a molten alloy phase, which separates by gravity from the unreduced management slag. The alloy is transferred to converters where, after the addition of further silica, the Mn and most of the Fe is reoxidized with air, separated as a slag, and recycled to the furnace. Gypsum, coke, and possibly sulfur are added to the alloy, producing a metal sulfide matte phase containing the Cu, Ni, and Co. These are separated in the converter and the slag is recycled to the electric furnace, while the matte is water quenched and granulated.

A ferromanganese alloy can be produced from the furnace slag by smelting, together with iron-rich slags and coke, in an electric furnace.

The metals are leached from the granulated matte with a 5 % H_2SO_4 solution in the presence of oxygen at 1 MPa and 110 °C. Copper and nickel are recovered separately from this solution by selective solvent extraction. The pH of the solution is controlled by addition of ammonia. The metals are stripped into acidic aqueous solutions and the products recovered by electrowinning.

Cobalt and the residual other metals are recovered from the aqueous ammonium sulfate solution by precipitation with hydrogen sulfide. The separated precipitate is contacted with air and H_2SO_4 at 100 °C to selectively redissolve the cobalt and residual nickel, which are recovered in powder form by selective reduction with hydrogen at 3.4 MPa and 185 °C.

9.4. Economic Viability and Future Prospects [78], [80–82], [88], [89]

The constraints inhibiting the exploitation of the nodule reserves are complex–a combination of economic, technological, sociological, and political. Any operation would have to satisfy several prerequisites: technical feasibility of mining and processing; economic or strategic viability; legal authorization and security of tenure; and environmental acceptability.

Although most of the results of the extensive research and development work undertaken by several nodule recovery consortia has not been published, sufficient successful announcements have been made to indicate that the recovery and processing of nodules is technically feasible.

Numerous environmental impact assessments indicate that nodule dredging totally destroys the area of operation. Adjacent undredged areas, however, appear to be unharmed and provide the basis for rehabilitation. Adverse environmental effects are therefore short-lived.

The estimated economic viability of mining and processing nodules has been well reported, covering a wide range of scenarios. Estimates of the internal rate of return range from 3 to 18 %, with the more studies showing lower rates. The high degree of risk associated with nodule exploitation probably necessitates a rate of return of ca. 30 % to warrant investment. The studies also exhibit very high sensitivity to variations in commodity prices, metal recoveries, and deposit grades. From an economic viewpoint only, it is most likely that nodules will not be mined and processed in the foreseeable future without significant financial incentives in the form of price supports, market protection, and tax breaks.

The considerable uncertainty currently existing as to the legal authorization for mining beyond the limits of national jurisdiction (that is, outside the EEZ) casts more doubt on the feasibility of commercial nodule mining for some

Figure 21. Smelting and sulfuric acid leach process

years to come. The prospects of commercial exploitation of the extensive deposits of cobalt-rich manganese oxide crusts lying within the EEZ are better than those for the nodules. The technical feasibility of recovering these crusts has not yet, however, been developed and tested.

The supply and demand situation, coupled to strategic considerations, for the four metals of interest will probably be the ultimate determining factor for future exploitation. Most mining consortia have only considered the recovery of cobalt, nickel, and copper. Recent reappraisals of manganese and its perceived value as a strategic metal (particularly in the United States) has led to an increasing interest in four-metal extraction. A modest increase in manganese usage is predicted in future, directly coupled to steel production. The perceptions of the instability of cobalt supply from African sources increase the strategic sensitivity of this metal.

Figure 22. Price of ferromanganese
—- Actual price; – – – Price in 1985 $

Another important use for nodules is as a stack gas absorption mechanism. Elimination or reduction of sulfur and nitrogen oxides is possible by catalytic oxidation by compositions involving transition metals. Nodules possess the high specific surface area and transition metal

oxide content required for an oxidation catalyst. This use of nodules also provides a primary stage for the recovery of the metals of value. The complex metal oxides in the nodules are readily reduced to sulfides as a contaminated gas stream is passed through the filter pack of ground nodules. Well defined processing techniques, as described before, can then be applied to recover the four metals of interest.

Figure 23. Price of silicomanganese
—- Actual price; – – – Price in 1985 $

10. Economic Aspects [90]

Ninety percent of manganese produced is consumed in the steel industry, and the growth of the manganese industry is therefore directly related to that of the steel industry. Steel production in the Western world dropped sharply in the early 1980s and bottomed out in 1982–1983. Economic recovery in the Western industrialized countries in the late 1980s resulted in strong growth in the steel sector. Between 1986 and 1988 the world production of crude steel increased by 9 percent to 780×10^6 t and is likely to continue at this level into 1990, when a drop off is expected. As a consequence the demand for ferromanganese alloys has increased considerably. The increase in demand placed upward pressure on the price of ferromanganese and silicomanganese in 1988 and 1989 and in terms of constant 1985 U.S. $ similar price levels are being achieved to those in the early 1980s (see Fig. 22). A sharp drop in the price of silicomanganese was experienced at the end of 1989 due to an excess of Chinese material in the market and the low ferrosilicon prices (see Fig. 23).

As steel demand is expected to flatten off in the 1990s high growth rates in the demand for manganese are not expected to continue. Improvements in the technology used in the steel industry will result in lower consumption of manganese alloys per tonne of steel. This trend will be further influenced by the development of the Optimal Refining Process (ORP) in Japan, in which manganese ore instead of alloys is added to the blast furnace runner prior to the basic oxygen furnace. In the short to medium term ferromanganese prices are likely to remain high due to the expected level of high-grade manganese ore prices. Silicomanganese prices should remain weak as the production of this material is not as dependent on high-grade ores and will continue to be influenced by the ferrosilicon price and availability.

The increased demand for ferromanganese alloys has highlighted the shortage in the production capacity of high-grade ores, and as a result large increases in the ore prices were seen in 1988 and 1989 (see Fig. 24). Demand for high-grade ores is likely to increase due to the additional demand materializing in the former Soviet Union, China and the Eastern-bloc countries.

1. Introduction [1]

Manganese compounds occur in all oxidation states from − 3 to + 7, with + 2, + 4, and + 7 being the most important. Most of the species in which Mn displays a negative valence state are anionic; for example, the ion $Mn(CO)^{3-}$ [obtained by vigorous reduction of $Mn_2(CO)_{10}$] contains Mn in the − 3 state. The − 2 oxidation state can be found in a complex of manganese with phthalocyanine, whereas manganese in the − 1 state is represented by the manganese pentacarbonyl ion $Mn(CO)_5^-$. Ions representing the various positive valences display characteristic colors, as indicated in Table 1. The color of a particular ion in solution is not always the same as that of the corresponding solid compound. Thus, solid MnO is light green, $Mn(OH)_2$ is white, and Mn_3O_4, Mn_2O_3, and MnO_2 are black. Liquid Mn_2O_7 is green under reflected light but deep red under transmitted light.

Given the multitude of valence states for manganese compounds, redox reactions are of great importance. Under suitable pH conditions, compounds containing manganese with a valence of + 3 or more are effective oxidants. Furthermore, tri-, penta-, and hexavalent manganese compounds tend to undergo disproportionation reactions under the influence of H^+ and OH^- :

$$2\,Mn^{3+} \rightarrow Mn^{2+} + Mn^{4+}$$
$$2\,Mn^{5+} \rightarrow Mn^{4+} + Mn^{6+}$$
$$3\,Mn^{6+} \rightarrow Mn^{4+} + 2\,Mn^{7+}$$

The divalent state is generally regarded as the most stable, at least in acid to neutral media. Tetravalent manganese is also quite stable as MnO_2 under moderately acid and moderately alkaline conditions, while the heptavalent state displays maximum stability around pH 7. Precipitated manganese(II) hydroxide is oxidized at room temperature by oxygen to tri- and tetravalent manganese oxides in the presence of traces of alkali, while conversion to manganates (i.e., the penta- and hexavalent states) requires much higher temperatures and high alkali concentrations ($\geq$ 180 °C for 60 – 70 % KOH). The basicity of the manganese oxides decreases (and the acidity increases) with increasing valency. Thus, MnO behaves as a basic anhydride, MnO_2 is amphoteric, and Mn_2O_7 is an acidic anhydride. Even though manganese in its highest valence state (+ 7) resembles chlorine (i.e., perchlorate), its general reactivity corresponds more closely to that of iron.

Table 1. Ionic species of manganese

Ion	Valence	Color
Mn^{2+}	+2	pink
Mn^{3+}	+3	red
Mn^{4+}	+4	brownish black
MnO_4^{3-}	+5	blue
MnO_4^{2-}	+6	green
MnO_4^{-}	+7	purple

2. Manganese Oxides

2.1. Manganese(IV) Oxide

2.1.1. Properties

Manganese(IV) oxide [*1313-13-9*], MnO_2, M_r 86.93, is deep black to dark brown and practically insoluble in water. It is more commonly referred to as manganese dioxide, occasionally as pyrolusite. Pyrolusite (German: Braunstein) is also the name of a specific MnO_2-containing mineral. The purest manganese dioxide – corresponding rather closely to the formula MnO_2 – occurs in the form known as the β-modification. The compositions of other natural or synthetic manganese dioxides range from $MnO_{1.7}$ to $MnO_{<2.0}$ with varying contents of lower-valent manganese, foreign cations (e.g., K^+, Na^+, Ba^{2+}), hydroxyl ions, and water molecules. At least six distinct modifications of manganese dioxide have been characterized (α, β, γ, δ, ε, and ramsdellite) [2], [3], which differ according to their degree of crystallization and their content of foreign ions. The β-modification (as in the mineral pyrolusite) is not only the least reactive form of MnO_2 but also the most highly crystalline, and it comes the closest to having a stoichiometric composition. By contrast, γ-MnO_2 is nearly amorphous and much more reactive both chemically and electrochemically. When heated up to 500 °C, manganese dioxides frequently release water and/or undergo phase transitions; above 500 °C they liberate oxygen. Between 500 °C and 600 °C MnO_2 is converted into Mn_2O_3, and above 890 °C into Mn_3O_4. Manganese dioxide acts as an oxidant toward readily oxidizable materials, its own valency changing from +4 to +3 or +2. For example, under acidic conditions manganese dioxide oxidizes chloride ions to chlorine; hydrazine and hydroxylamine to nitrogen; iron(II) to iron(III); carbon monoxide to carbon dioxide; alkylbenzenes to aromatic carboxylic acids, ketones, and, in some cases, aldehydes; and oxalic acid to carbon dioxide.

In the presence of strong alkalis and at elevated temperature, however, manganese dioxide is itself readily oxidized by oxygen to manganese(V) and (VI) compounds. Other noteworthy properties of the various MnO_2 modifications include their sorptive and ion-exchange capabilities and their catalytic and electrochemical activities. The latter is of great importance to the dry-cell battery industry, which consumes large amounts of "battery-active" MnO_2 (especially the γ- and ε-modifications) for use as a depolarizer (→ Batteries, Chap. 6.1.3.1.

2.1.2. Natural Manganese Dioxide

Only about 5 % of the world production of manganese ore (totalling about 27×10^6 t/a) is consumed in nonmetallurgical applications. In 1976, the following approximate tonnages of manganese ore were associated with applications other than steel making [4, p. 331]:

For dry cell batteries (battery-active ore plus ore consumed in the production of battery-grade electrolytic manganese dioxide and chemical manganese dioxide)	500 000 t/a
In brick and ceramic coloring, including in glass manufacture	200 000 t/a
In welding rod manufacture	200 000 t/a
For the production of Mn chemicals and diverse chemical and metallurgical products	450 000 t/a
Total	1 350 000 t/a

Within limits, these consumption figures are probably still applicable, because world ore consumption in 1976 (24×10^6 t/a) was only slightly less than that in 1986 (25×10^6 t/a), and about 5 % is still consigned to metallurgical uses. Organic MnO_2 oxidations are generally carried out in the presence of sulfuric acid, and they lead to manganese sulfate as a byproduct (see Chap. 3). Oxidation of aniline by MnO_2 in the presence of sulfuric acid was once the main industrial route to hydroquinone, but since the late 1960 s this technique has been largely replaced by other methods, at least in the Western world. For more information on the synthetic applications of native manganese dioxide, see [5, pp. 36 – 37].

Several processes are known for the recovery of manganese from low-grade MnO_2-containing ores (Mn content < 20 wt %) [6, pp. 727 – 731], [7], but they are currently of little practical significance since high-grade manganese ores (Mn > 40 wt %) are widely available at moderate prices.

2.1.3. Synthetic Manganese Dioxides

2.1.3.1. Commercial Forms

Several types of synthetic manganese dioxide are produced commercially for specific end uses. In principle, synthetic manganese dioxide can be prepared either by a strictly chemical route (*chemical manganese dioxide, CMD*) or by electrochemical methods (*electrolytic manganese dioxide, EMD*).

Procedures leading to CMD include the oxidation of Mn(II) salts or lower manganese oxides, reduction of permanganates, thermal decomposition of manganese(II) nitrates, thermal decomposition/oxidation of manganese carbonate, and disproportionation of Mn(III) compounds.

Manganese dioxides obtained by reduction of permanganate are commonly known as *manganites*. They correspond to the δ-modification of MnO_2 and should actually be regarded as salt-like combinations of hydrous manganese dioxide and cations of base-forming metals (e.g., $K_2O \cdot 4\,MnO_2$). The metal portion is exchangeable against other cations. Such manganites [which are actually alkali manganates(IV)] are often obtained as byproducts from technical permanganate oxidations, but they may also be synthesized intentionally by direct reduction of permanganate (e.g., with manganese(II) salts). Until the late 1960 s, the manganites were important in the manufacture of dry cells because they are highly active depolarizers. Manganites for this purpose were produced and sold in Europe under such trade names as Manganit and Permanox. However, in recent years they have been largely displaced by electrolytic manganese dioxide (EMD) and the other types of chemically prepared manganese dioxide (CMD) described in Section 2.1.3.2.

Also of interest is the *hydrated manganite,* better known as *active manganese dioxide,* used in organic syntheses under nonaqueous, neutral conditions. Manganese dioxide of this type is generally prepared from $MnSO_4$ and $KMnO_4$ under strictly controlled conditions. Numerous methods are available for the preparation of "active" manganese dioxide. Many involve oxidation of a Mn^{2+} salt with $KMnO_4$, but $NaClO_3$ or O_3 are also used as oxidants. In a typical procedure, a solution of manganese sulfate (151 g/2.87 L) is added with stirring to a solution of potassium permanganate (105 g/2 L), and the resulting suspension of hydrous MnO_2 is stirred at 60 °C for 1 h. After filtration and washing, the precipitate is dried to a constant weight at 60 °C [8, p. 122]. These conditions lead to precipitated MnO_2 in the poorly crystallized but very reactive γ-form. It is a specific oxidant whose uses include dehydrogenation (e.g., the preparation of unsaturated aldehydes and ketones from unsaturated alcohols) and coupling reactions.

Figure 1. Manufacture of high-purity manganese dioxide MnO_2 (Chemetals process)

Mention should also be made of the increasing use of manganese-dioxide-based *oxidation catalysts*, particularly for air pollution abatement (removal of volatile organics, destruction of ozone) [9], [10].

Another commercial CMD is a *high-purity manganese dioxide* used in the manufacture of high-purity lower manganese oxides as well as ferrites (ceramic magnets) and thermistors for the electronics industry. This product (99.5 wt %

MnO_2) is obtained by thermal decomposition of manganese nitrate:

$$Mn(NO_3)_2 \overset{H_2O}{\rightleftharpoons} MnO_2 + 2\,NO_2$$

For a description of the original manganese nitrate process developed by IG Farbenindustrie (Bitterfeld) in the 1920 s, see [11]. A later modification of this process by Chemetals has been utilized at a plant in Baltimore since the early 1970 s [12], [13] (Fig. 1).

A concentrated solution of manganese nitrate (made from MnO_2 ore by reaction with NO_2) is first purified and then thermally decomposed at about 140 °C in a well-agitated, externally heated reactor. The resulting β-manganese dioxide precipitates as a fine, free-flowing powder; the nitrogen dioxide coproduct is recycled to generate new manganese nitrate. Chemetals' production capacity for high-purity manganese dioxide is about 6000 t/a.

2.1.3.2. Synthetic Manganese Dioxides for Dry Cells

From a commercial standpoint the most important synthetic manganese dioxides are those that are electrochemically active and are therefore useful as depolarizers in dry-cell batteries. Electrochemical or battery activity of MnO_2 results from a favorable combination of such factors as crystal structure, surface area, porosity, and chemical purity. Battery activity is not readily predictable; the only reliable way of establishing this property is by an actual performance test in a battery.

One important type is the so-called *activated manganese ore*, actually a semisynthetic product. It is made by roasting a high-grade oxidic manganese ore containing at least 80 wt % MnO_2 but with low or no battery activity at 600 °C. The product is then treated with hot sulfuric acid.

$$2\,MnO_2 \xrightarrow{600\,°C} Mn_2O_3 + 1/2\,O_2$$

$$Mn_2O_3 + H_2SO_4 \longrightarrow MnO_2 + MnSO_4 + H_2O$$

The second reaction is a disproportionation of trivalent manganese leading directly to battery-active γ-MnO_2. The coproduct $MnSO_4$ must be separated by leaching with water. Activated manganese ore is somewhat less effective as a depolarizer than EMD or fully synthetic CMD (see below), but it is still produced in France at a rate of several thousand tonnes per year under the names Ergogene and Philodyne.

Chemical Manganese Dioxide (CMD). Much more important than activated ores are the CMD products manufactured by the Sedema Division of Sadacem S.A. in Belgium under the trade names Faradiser M (for Leclanché and magnesium cells) and Faradiser WSZ (for zinc chloride batteries). The chemical compositions of the two products are practically identical: ca. 90 wt % MnO_2 (primarily the γ-modification), 2 wt % water, plus minor amounts of lower manganese oxides. Critical trace impurities (Co, Ni, Cu, Mo) are kept below 0.001 wt %. Types M and WSZ differ in such physical properties as surface area and density. Typical particle sizes are 80 % $<$ 44 µm for type M and 85 % $<$ 44 µm for type WSZ.

The first step in the production process [13], [14] (Fig. 2) is the reduction of MnO_2 ore to MnO using heavy fuel oil and a temperature of ca. 900 °C. The MnO is then treated with sulfuric acid to form manganese(II) sulfate. After careful neutralization with MnO to precipitate heavy metal impurities, solids are removed by thickening. The solution of $MnSO_4$ is then treated with ammonium carbonate (by simultaneous addition of NH_3 and CO_2) to precipitate manganese(II) carbonate, ammonium sulfate being generated as a byproduct. The $MnCO_3$ is separated and dry-roasted in the presence of air at about 320 °C to form a higher manganese oxide with the approximate composition $MnO_{1.80-1.85}$. Complete oxidation to MnO_2 is achieved by treatment with $NaClO_3$ in the presence of sulfuric acid. The key oxidation reactions may be represented as

$$MnCO_3 \xrightarrow{320\,°C} MnO_{1.85} + CO_2$$

$$MnO_{1.85} + NaClO_3 \xrightarrow{H_2SO_4} MnO_2 + Cl_2$$

Sedema introduced a process improvement in the course of expanding their production in which the MnO_2 is transformed directly to $Mn(NO_3)_2$ by reaction with nitric oxides. The procedure is similar to the first step in the

Figure 2. Production of chemical manganese dioxide (CMD) according to the Sedema process [13]

Chemetals synthesis of high-purity manganese dioxide (see Section 2.1.3.1). The $Mn(NO_3)_2$ solution thus obtained is treated with ammonium carbonate to give manganese carbonate (processed as before) and ammonium nitrate. The latter byproduct is more readily marketed as a fertilizer than the previously obtained manganese sulfate [15].

Electrolytic manganese dioxide (EMD) is the most important of the synthetic manganese dioxides even though it is a relatively new commodity. Practically all the EMD produced is used in the manufacture of dry cells and electronic materials such as ferrites.

The electrolytic preparation of MnO_2 was discovered during the first half of the 19th century, but the outstanding suitability of the product as a depolarizer for dry cell batteries was not recognized until 1918 [16]. Commercial production started in Japan and the United States during the 1930 s. By about 1952 the Japanese industry had perfected their technology to such an extent that the performance of dry cells made with EMD was about two to three times that of cells made with native battery ore [17]. Ever since, the Japanese EMD industry has maintained its world leadership in this field.

Electrolytic manganese dioxide is a black powder and typically contains 91 wt % MnO_2 (mostly the hexagonal ε-modification [18]), 3 – 5 wt % moisture, up to 1.3 wt % sulfate, < 0.02 wt % Fe, and very low residual concentrations (< 0.001 wt %) of such metals as Pb, Cu, and Co. The balance consists largely of lower manganese oxides. The true density of EMD ranges from 4.0 to 4.3 g/cm^3, and its tap density from 2.2 to 2.3 g/cm^3. The BET surface area is 40 – 50 m^2/g [17] with a particle size of < 74 µm (< 200 mesh).

The outstanding performance of EMD as a battery depolarizer (especially in high-performance alkaline cells) is a result of its unique solid state properties (which permit free transport of protons through the lattice) and the virtual absence of elements that promote the corrosion of zinc metal [19].

Production of EMD usually starts from manganese dioxide ore [13], [20, p. 385], [21, p. 637], [22] (Fig. 3), which is first reduced to MnO with either coal, heavy fuel oil, hydrogen, or natural gas. The MnO is then leached with sulfuric acid to form a manganese sulfate solution. Alternatively, if the rhodochrosite (manganese carbonate) is the starting material (as in Japan), only a leaching step with sulfuric acid is required. The acidic manganese sulfate solution is then purified by oxidation with MnO_2 and neutralized with lime to a pH of 4 – 6. This treatment precipitates any heavy-metal ions present (Fe, Pb, Ni, Co). Hydrogen sulfide may be added for even more complete purification. After filtration and adjustment of concentrations to 75 – 160 g/L $MnSO_4$ and 50 – 100 g/L H_2SO_4, the manganese sulfate solution is subjected to electrolysis, which can be represented in simplified form by the following reactions:

$$\text{Anode:}\quad Mn^{2+} + 2\,H_2O \rightarrow MnO_2 + 4\,H^+ + 2\,e^-$$
$$\text{Cathode:}\quad 2\,H^+ + 2\,e^- \rightarrow H_2$$
$$\text{Overall:}\quad Mn^{2+} + 2\,H_2O \rightarrow MnO_2 + 2\,H^+ + H_2$$

The electrolytic cells generally consist of open steel troughs equipped with an acid-resistant, electrically nonconductive lining (e.g., Hypalon, rubber, or ceramic). The anode is made from graphite, hard lead, or titanium. Anode current density is 70 – 120 A/m^2 at a cell voltage of 2.2 – 3.0 V. During the electrolysis, which is carried out at 90 – 98 °C (a paraffin layer is used to minimize evaporation), the concentration of $MnSO_4$ decreases and that of H_2SO_4 increases. Current yields range from 70 % in older installations to > 90 % in modern plants. In practically all commercial processes the EMD is deposited as a solid coating on the anode.

Electrolysis is terminated when the EMD deposit is 20 – 30 mm thick (requiring 14 – 20 d). The product is then mechanically removed from the anode, crushed, repeatedly washed with hot water, dried, and ground to the desired particle size (which depends upon the grade). The ground product is resuspended in water, adjusted to pH 6.5 – 7.0 with alkali, dried at 85 °C to a defined residual water content, and packaged.

Much of the recent progress toward economical production of high-quality EMD is related to technical advances in electrolytic cell (especially electrode) technology. Nevertheless, many EMD producers still use graphite and lead anodes (Table 2). The main disadvantage of graphite anodes lies in their relatively short life; lead anodes lead to undesirable product contamination. The modern trend is toward titanium an-

Figure 3. Production of electrolytic manganese dioxide (EMD) according to the process used by Tekkosha, Greece [13]

Table 2. Major producers of electrolytic manganese dioxide (EMD)

Country	Producer	Location	Production capacity, 10^3 t/a∗	Anode material [23]
Japan	Toyo Soda	Hyuga	24	Ti
Japan	Mitsui Mining and Smelting	Takehara	24	Ti
Japan	Dai-Ichi Carbon Company	Yokohama	6	C
Japan	Japan Metals and Chemicals Company	Takaoka	18	Ti
Greece	Tekkosha Hellas	Thessaloniki	15	C
Ireland	Mitsui Denman	Cork	12	Ti
United States	Kerr McGee	Henderson, NV	14.5	C

Brazil	Union Carbide	Itapercerica	4	C
South Africa	Delta	Nelspruit	12	Pb
Total world capacity			194.5	

∗ Compiled by Hoechst AG, 1987.[86]

odes, which are mechanically and chemically stable and do not cause product contamination. One of the apparent limitations of titanium anodes is the formation of a passivated layer on the electrode surface at current densities $> 80-90\ A/m^2$, but this problem has been overcome by the addition of a mixture of finely ground manganese oxides (MnO_2, Mn_2O_3, Mn_3O_4) to the electrolyte [24]. Cells are now operated at current densities $\geq 150\ A/m^2$, resulting in a substantial increase in productivity.

Economic Aspects. World capacity for CMD is estimated to be ca. 40 000 t/a. This includes the Sedema Division of Sadacem in Belgium, Chemetals Corporation in the United States, and several plants in the former Soviet Union. Actual consumption is about 25 000 t/a [25]. Even though CMD has its own established niches in the battery industry, it also competes increasingly with EMD as a depolarizer in high-performance cells.

Electrochemical manganese dioxide is now the most important fastest growing synthetic manganese product due to the high growth rate of the dry-cell battery and electronic component markets. World production capacity for EMD is approximately 183 000 t/a (Table 2) and growing. The EMD capacities in Japan and the United States are 73 000 and 32 000 t/a, respectively. Additionally, two Japanese companies operate EMD plants in Ireland and Greece, with a combined capacity of ca. 25 000 t/a.

In view of the rapid growth of the EMD market in the 1980 s (averaging about 10 %/a), considerable interest has been stimulated in establishing new EMD production plants. Thus, announcements regarding the construction of new facilities were recently made by BHP in Australia (15 000 t/a), Metalman in Brazil (12 000 t/a), and CIA Minera Autlan in Mexico (13 200 t/a).

According to [26], the 1986 world demand for EMD was about 128 000 t/a, and current production is said to be 165 000 t/a [25]. Serious EMD oversupply and fierce competition among producers is already evident, and is expected to intensify in the future.

2.2. Other Manganese Oxides

Manganese(II) Oxide. Manganese(II) oxide [*1344-43-0*], manganese monoxide, MnO, M_r 70.94, green, ϱ 5.37 g/cm^3, *mp* 1945 °C, is practically insoluble in water and occurs in nature as manganosite. It dissolves readily in most acids. Synthetic manganese monoxide is obtained by reduction of manganese dioxide or by thermal decomposition of Mn(II) carbonate

under the exclusion of air. Depending on particle size (a function of the method of preparation), MnO reacts at varying rates with atmospheric oxygen even at room temperature, thereby forming Mn_3O_4.

Manganese monoxide has major significance as an intermediate in the manufacture of Mn(II) compounds (especially manganese sulfate and sequential products) from MnO_2 ores. Reducing agents for MnO_2 in the large-scale manufacture of manganese monoxide include finely powdered coal, hydrogen, carbon monoxide, natural gas, and heavy fuel oils. The reaction is carried out at 400 – 800 °C in a rotary kiln or shaft furnace. The freshly formed manganese oxide must be allowed to cool in a reducing atmosphere in order to ensure room-temperature stability with respect to atmospheric oxygen.

Manganese monoxide (in contrast to manganese dioxide) is readily assimilated by most plants. This fact accounts for its widespread use as a fertilizer for manganese-deficient soils (→ Fertilizers, → Fertilizers, Chap. 4.3.1.).

The consumption of manganese monoxide in the United States for fertilizer applications (alone or in combination with $MnSO_4$) is about 20 000 t/a. A similar amount is used as an animal feed additive (→ Foods 1. Survey, Chap. 3.5., → Foods 1. Survey, Chap. 6.3.). Fertilizer/feed grade manganese monoxide (containing 77 wt % MnO) is made by direct reduction of manganese ore.

High-purity manganese monoxide (obtained, for example, by reduction of 99.5 % MnO_2) is used in the production of specialty ceramics and glasses for electronic applications, in ferrites and thermistors, and for making welding rod fluxes and high-purity manganese chemicals.

Manganese(III) Oxide. Manganese(III) oxide [*1317-34-6*], Mn_2O_3, M_r 157.86, decomp. > 900 °C, ϱ 4.89 g/cm^3, exists in α- (rhombic or cubic) and γ- (tetragonal) modifications. The hydrate $Mn_2O_3 \cdot H_2O$ [*1332-63-4*] occurs as the mineral manganite and forms steel-gray, shiny, rhombic crystals. Manganese(III) oxide is made industrially from manganese dioxide by calcination at 600 – 800 °C, or by thermal decomposition and controlled air oxidation of manganese carbonate. Primary uses are the preparation of such electronic materials as ceramic magnets and semiconductors. It is a small-volume product, a few hundred tonnes are consumed annually.

Manganese(II, III) Oxide. Manganese(II, III) oxide [*1317-35-7*], Mn_3O_4, M_r 228.79, *mp* 1562 °C, occurs naturally as hausmannite and crystallizes tetragonally (ϱ 4.84 g/cm^3). It may be obtained from the other manganese oxides by heating above 950 °C in the presence of air. According to [27], high-purity Mn_3O_4 can also be made from an aqueous suspension of finely divided manganese metal by air oxidation at 30 – 100 °C in the presence of ammonium salts. The compound forms black crystals, but finely dispersed it appears as a red powder. Highly purified Mn_3O_4 is used in the manufacture of semiconductors and ceramic magnets. World production is estimated at ca. 2000 t/a.

Other Manganese Oxides. Oxides with penta-, hexa-, or heptavalent manganese have no industrial significance. Indeed, the hypothetical oxides Mn_2O_5 and MnO_3 have never been prepared. The anhydride of permanganic acid, Mn_2O_7, forms readily from $KMnO_4$ and concentrated sulfuric acid. It is an unstable, highly explosive, green-black liquid.

3. Manganese(II) Salts

Manganese acetate [*15243-27-3*], $Mn(CH_3COO)_2 \cdot 4\,H_2O$, M_r 245.08, ϱ 1.589 g/cm^3, forms pink crystals that are soluble in water, methanol, and ethanol. The compound dehydrates between 80 °C and 130 °C, and decomposes at 350 °C to Mn_2O_3. It is made industrially from acetic acid and either manganese carbonate, manganese(II) oxide, or electrolytic manganese metal. Its main use is as a catalyst (either alone or in combination with cobalt) in the liquid-phase air oxidation of hydrocarbons to carboxylic acids.

Manganese borate [*12228-91-0*], $MnB_4O_7 \cdot 8\,H_2O$, M_r 354.34, is a white to pale reddish-white solid. It is insoluble in water and ethanol, but soluble in dilute acids. The compound is precipitated from aqueous solutions of manganese chloride and sodium borate, and is used as a siccative.

Manganese(II) carbonate [*598-62-9*], $MnCO_3$, M_r 114.94, light pink, decomp. > 200 °C, ϱ 3.125 g/cm^3, occurs naturally as rhodochrosite. It is sparingly soluble in water (solubility product at 25 °C: 8.8×10^{-11}) but readily soluble in acids. It is produced commercially from manganese sulfate by precipitation with alkali-metal carbonates or hydrogen carbonates. If the presence of alkali-metal ions must be avoided in the product (as in the manufacture of ferrites), ammonium hydrogen carbonate may be used as the precipitating agent. According to a GDR patent [28], the use of ferromanganese as a starting material results in manganese carbonate of especially high purity. The precipitated $MnCO_3$ is filtered, washed, and dried at 110–120 °C. Heating above 200 °C causes decomposition to MnO and CO_2.

Manganese carbonate is used in the synthesis of other manganese(II) salts (by reaction with the corresponding acids) and also in the production of battery-active, chemical manganese dioxide (CMD) (see page 4). Manganese carbonate is also important in the preparation of high-quality manganese – zinc ferrites for the television and computer industries [4, p. 180]. World production of $MnCO_3$ is estimated to be about 9000–10 000 t/a.

Manganese(II) chloride [*7773-01-5*], $MnCl_2$, M_r 125.84, ϱ 2.977 g/cm^3, *mp* 690 °C, *bp* 1190 °C, is readily soluble in water and exists in the anhydrous form and as di-, tetra-, and hexahydrates. Unless precautions are taken (see below), thermal dehydration of the hydrates to the anhydrous form may result in some hydrolytic decomposition, with formation of gaseous HCl and manganese oxychloride.

Industrial preparation of manganese chloride is based either on the reaction of aqueous hydrochloric acid with MnO_2 ore, MnO, $MnCO_3$ (rhodochrosite), or on direct chlorination of manganese metal or ferromanganese. The process formerly employed in Bitterfeld (GDR) started from manganese ore (MnO_2). Chlorine gas is generated

$$MnO_2 + 4\,HCl \rightarrow MnCl_2 + Cl_2 + 2\,H_2O$$

and is absorbed in a suspension of hydrated lime [6, p. 739]. An alternative process used by Chemetals avoids the formation of chlorine by prereduction of the MnO_2 to MnO.

The $MnCl_2$ solution thus obtained is purified by neutralization with $MnCO_3$, causing iron and aluminum impurities to precipitate. After filtration and evaporation, the tetrahydrate crystallizes from the cooled solution in plate-like crystals. This material, which is itself a commercial product, requires very careful drying because it melts at 58 °C in its own water of crystallization. Dehydration requires a temperature above 200 °C. Fusion in the oven is avoided by addition of previously dehydrated product. The drying process may be carried out in the presence of excess dry HCl gas if anhydrous manganese chloride free of oxychlorides is required.

Uses of manganese(II) chloride include dry cell manufacture, preparation of hard and corrosion-resistant magnesium alloys, synthesis of methylcyclopentadienylmanganese tricarbonyl (Chap. 5) and brick coloring [4, p. 182].

Manganese(II) nitrate [*10377-66-9*], $Mn(NO_3)_2$, M_r 169.02, decomp. > 140 °C, exists in the anhydrous form and as mono-, tri-, tetra-, and hexahydrates. The commercial product is the tetrahydrate [*20694-39-7*], which is readily soluble in water. Manganese nitrate is prepared by nitric acid treatment of manganese carbonate or MnO, or by reaction of MnO_2 with nitric oxides. The compound is an important intermediate in the production of high-purity manganese oxides and is also used in the preparation of colorants for the ceramics industry.

Manganese(II) Phosphates. The most important manganese phosphate is the water-soluble $Mn(H_2PO_4)_2\cdot 2\,H_2O$ [*18718-07-5*], which is prepared by dissolving manganese carbonate, manganese(II) oxide, or manganese metal in phosphoric acid. This phosphate finds wide application in the phosphatizing of ferrous metals and is also used as a light stabilizer for polyamide fibers.

Manganese(II) sulfate [*7785-87-7*], $MnSO_4$, M_r 151.01, ϱ 3.25 g/cm^3, *mp* 700 °C, *bp* 850 °C (decomp.), is almost pure white in the anhydrous state; the corresponding mono-, tetra-, penta-, and heptahydrates are pink. Manganese(II) sulfate is readily soluble in water, but has a strongly negative solubility coefficient at temperatures > 24 °C. The solids content of a

manganese sulfate solution saturated at 24 °C is 39.3 wt %; at 100 °C the solids content drops to 26.2 wt %.

The customary commercial product (technical grade) is the monohydrate, containing 99 wt % $MnSO_4 \cdot H_2O$. Manganese sulfate is produced either directly by reaction of manganese(II) oxide (or manganese carbonate) with sulfuric acid or as a byproduct from organic oxidations with manganese dioxide.

Until recently the manufacture of hydroquinone (by oxidation of aniline with MnO_2 and H_2SO_4) was a major source of fertilizer-grade manganese sulfate, containing 78 wt % $MnSO_4$ [29], but modern hydroquinone processes are based on either diisopropylbenzene/O_2 or phenol and H_2O_2 (→ Hydroquinone).

Before 1977 Tennessee Eastman, a major U.S. hydroquinone producer, operated with a byproduct manganese sulfate capacity of about 35 000 t/a. Eastman's manufacturing technology has since been changed, and manganese sulfate is no longer produced. Other organic oxidations are still carried out with MnO_2 as the oxidant (e.g., the manufacture of 4-*tert*-butylbenzaldehyde and *p*-anisaldehyde), but the output of manganese sulfate from these processes is no more than a few thousand tonnes per year, so the majority of U.S. manganese sulfate is now derived directly from MnO or $MnCO_3$.

Manganese sulfate is commercially one of the most important manganese products. It is the starting material for electrolytic manganese metal, electrolytic manganese dioxide, fungicides such as Maneb (→ Fungicides), and other manganese compounds including manganese carbonate, manganese soaps (naphthenate, linolate, and resinate, all used as siccatives), and certain inorganic pigments. Manganese sulfate is also used in textile printing and glass making. Very significant in terms of volume is the use of manganese sulfate as a fertilizer for manganese-deficient soils, for example, in the vegetable- and citrus-growing areas of Florida. It is also valuable as a micronutrient additive for animal feeds [4, p. 187].

World production of commercial manganese sulfate is estimated to be about 120 000 – 130 000 t/a. Production in the United States is ca. 8000 t/a, with a demand of approximately 14 000 – 14 500 t/a. The deficit is covered by imports from Europe and the People's Republic of China.

Major producers of manganese sulfate include: Eagle Picher (USA), production capacity 6000 t/a; Sulfamex (Mexico) 21 000 t/a (start-up delayed); and Sedema (Belgium) 22 000 t/a. For more economic information on manganese sulfate, see [30].

4. Higher Oxidation-State Manganates

4.1. Potassium Manganates(V) and (VI)

Potassium manganate(V) [*12142-41-5*], K_3MnO_4, M_r 236.24, ϱ 2.78 g/cm^3, decomp. > 1000 °C, occurs as fine blue-green to turquoise crystals. In the presence of water it is readily hydrolyzed, disproportionating to K_2MnO_4, $KMnO_4$, and MnO_2. Solutions of K_3MnO_4 in 40 % potassium hydroxide have limited stability even below − 10 °C; however, in the presence of 75 % KOH and under nitrogen, potassium manganate(V) is stable up to 240 °C. Pure potassium manganate(V) can be heated to over 900 °C without decomposition. It is an important intermediate in the production of potassium permanganate.

Potassium manganate(VI) [*10294-64-1*], K_2MnO_4, M_r 197.14, ϱ 2.703 g/cm^3, decomp. 640 – 680 °C, exists in the pure state as brilliantly green, rhombic crystals. Upon aging, the color changes to black-green due to the formation of a surface film of $KMnO_4$. The compound is less prone to decomposition than K_3MnO_4; the deep green solutions in 15 – 20 % potassium hydroxide (for solubilities in KOH see [31]) are quite stable even at 50 – 60 °C. In more dilute solutions, and especially in the presence of acid, K_2MnO_4 disproportionates to $KMnO_4$ and MnO_2. Pure potassium manganate(VI) is stable up to ca. 600 °C; at higher temperatures it loses oxygen to form K_3MnO_4 and Mn_2O_3. By far the largest part of the K_2MnO_4 produced industrially is converted to potassium permanganate; smaller quantities are used in the surface treatment of magnesium metal [32] and as a chemical oxidant [5, p. 175].

4.2. Potassium Permanganate

The best known of the manganates, potassium manganate(VII) (potassium permanganate) was introduced as a commercial product in 1862 [33]. It soon became a very important chemical [34] not only industrially but also in the eyes of many generations of academic and industrial researchers. The former concerned themselves with the chemistry of $KMnO_4$ and its precursors, while the latter devised new and improved methods for its production. Unraveling the chemistry of the higher valence states of manganese (generally referred to as manganates) proved to be a major challenge. Since 1954 the roles of the various manganates [especially manganate(V)] in the industrial production of $KMnO_4$ have been fully clarified [35]. For more detailed historical information, see [36].

4.2.1. Properties

Potassium manganate(VII) [*7722-64-7*], $KMnO_4$, M_r 158.03, ϱ 2.703 g/cm^3, decomp. $>200\,°C$, gives dark purple to bronze-colored rhombic crystals. Its solutions are faint pink to deep violet, depending on concentration. The solids content of a saturated aqueous solution at 20 °C is ca. 6 wt % $KMnO_4$ (11 wt % at 40 °C and 20 wt % at 65 °C). Permanganate solutions are most stable in the neutral or near-neutral pH region; acidic or alkaline solutions decompose with loss of oxygen. For solubilities in aqueous KOH see [31]. Potassium permanganate is also soluble in several organic solvents, including acetone, glacial acetic acid, methanol, and sulfolane (tetrahydrothiophene-1,1-dioxide). Such solutions usually have limited stability because the permanganate ion slowly attacks the solvent.

When dry potassium permanganate is heated to 200–300 °C, an exothermic, autocatalytic decomposition takes place with the evolution of oxygen. Contact with combustibles, especially water-soluble organic substances (such as polyhydroxy compounds), can lead to spontaneous ignition and potentially violent combustion.

The usefulness of permanganate as an oxidant is a result of several unique properties. One is the compound's ability to function as an oxidant at all pHs. Also interesting is the fact that permanganate oxidations can be carried out in both aqueous and several nonaqueous solvents. Phase-transfer catalysis greatly extends the range of usable solvents [37].

Permanganate oxidizes a wide variety of inorganic and organic compounds (→ Oxidation). It is often regarded as the oxidant of choice for olefins and aromatic side chains even though it can also interact with other functional groups [5, pp. 183–288], [38]. Permanganate oxidations can be used not only for specific modification of organic molecules but also to destroy such materials as in pollution abatement applications.

In moderately alkaline, neutral, or slightly acidic media, $KMnO_4$ donates active oxygen according to the following equation:

$$2\,MnO_4^- + H_2O \rightarrow 2\,OH^- + 2\,MnO_2 + 3\,[O]$$

Only under substantially more acidic conditions, and with particular substrates, does permanganate oxidation follow an alternative course:

$$2\,MnO_4^- + 5\,H_2O + 6\,H^+ \rightarrow 2\,Mn^{2+} + 8\,H_2O + 5\,[O]$$

4.2.2. Production [6, pp. 741–762]

Most permanganate is made from MnO_2-containing ore by fusion followed by electrolysis. However, all-electrolytic methods also exist. One such method, practiced in the Soviet Union since the late 1950 s, involves direct single-step anodic oxidation of ferromanganese to permanganate [39]:

$$2\,Mn + 2\,OH^- + 6\,H_2O \rightarrow 2\,MnO_4^- + 7\,H_2$$

This process is not generally considered economical because of high energy consumption (about 15 kWh/kg), the high cost of preparing cast ferromanganese anodes, and the cost of cooling the electrolyte to the required operating temperature (20 °C).

In another patented all-electrolytic process [40] a 10–25 wt % suspension of precipitated manganese dioxide in aqueous KOH is electrolyzed at $\geq 60\,°C$:

$$MnO_2 + KOH + H_2O \rightarrow KMnO_4 + 3/2\,H_2$$

It is not clear whether this process is, or has been, used commercially.

4.2.2.1. Fusion Processes [41]

The industrial preparation of potassium permanganate and its precursors (K_3MnO_4 and K_2MnO_4) begins with a finely ground MnO_2 ore which is subjected to alkaline oxidative fusion:

$$2\,MnO_2 + 6\,KOH + 1/2\,O_2 \rightarrow 2\,K_3MnO_4 + 3\,H_2O \quad (1)$$
$$2\,K_3MnO_4 + H_2O + 1/2\,O_2 \rightleftharpoons 2\,K_2MnO_4 + 2\,KOH \quad (2)$$
$$MnO_2 + 2\,KOH + 1/2\,O_2 \rightarrow K_2MnO_4 + H_2O \quad (3)$$

In a separate step, potassium manganate(VI) is subsequently converted to potassium permanganate, usually by anodic oxidation (see Section 4.2.2.2).

Several continuous or batch-type fusion processes are in current use, but they may be categorized in two groups:

1) *Roasting processes* that employ a MnO_2: KOH molar ratio of 1 : 2 to 1 : 3 (the reaction mixture is a solid).
2) *Liquid-phase processes* with a MnO_2: KOH molar ratio $\geq$ 1 : 5.

Roasting processes usually involve two steps, with reactions (1) and (2) carried out sequentially. In the primary step, finely ground manganese dioxide is mixed with 50 % KOH (frequently in a highly dispersed form) and treated with air or oxygen at 300 – 400 °C. The KOH/MnO_2 reaction mixture is usually introduced as a fine spray into internally or externally heated rotary kilns (see Fig. 4). Stationary spray drier-like reactors are also in use. Most of the water quickly evaporates, and the highly concentrated KOH reacts within a few minutes with MnO_2 and oxygen to form K_3MnO_4 (Eq. 1). The dry, blue-green reaction product is ground to increase its surface area and then subjected to secondary oxidation (Eq. 2), in which it is exposed to a moisture-laden air or oxygen stream at 190 – 210 °C. Several hours are required to effect nearly complete conversion to the black-green K_2MnO_4.

Rotary kilns are commonly employed for this step, but other types of solid – gas contactor (e.g., specially designed "plate" reactors) are also utilized. The removal of hard crusts that form on the inner walls of the reactor can cause substantial downtime.

Figure 4. Rotary kiln with internal heating for the production of potassium manganate(VI)

Figure 5. Production of potassium permanganate: liquid-phase oxidation process (overall flow schematic)

Liquid-Phase Processes. In liquid-phase processes (see Fig. 5) finely ground MnO_2 ore is added to an excess of concentrated, molten

potassium hydroxide (70 – 90 wt %) at 200 – 350 °C. The reaction mixture is agitated vigorously and a stream of finely dispersed air or oxygen is passed through the molten mass. The MnO_2 is converted to K_2MnO_4 in a single step (Eq. 3), although such an oxidation can also be effected in two stages [42–44]. Potassium manganate(VI) crystallizes from the melt, from which it must then be separated by suitable means (e.g., thickening, decantation, filtration, and centrifugation) [45, p. 870].

4.2.2.2. Anodic Oxidation of Manganate(VI)

Oxidation of the manganate(VI) to permanganate is always accomplished by electrolysis:

$$K_2MnO_4 + H_2O \rightarrow KMnO_4 + KOH + 1/2\,H_2 \quad (4)$$

Crude manganate from the fusion process is first leached in dilute potassium hydroxide (90 – 250 g KOH per liter, depending upon the nature of the subsequent electrolysis). The resulting leach solution is usually filtered to separate insolubles, originating from the gangue portion of the ore (see Fig. 5).

Effective control of key parameters is decisive for the overall success of the electrolysis, including the concentrations of K_2MnO_4, $KMnO_4$, and KOH, as well as the temperature (usually ca. 60 °C).

Cell Design. Typical electrolysis cells employ voltages of 2.3 – 3.8 V and anodic current densities of 50 – 1500 A/m^2. Current yield depends on cell design and mode of operation, and ranges from 40 – 90 %. Nickel or Monel Metal are the preferred materials for the anode, whereas iron is usually the metal of choice for the cathode.

Cells may be either monopolar or bipolar, rectangular or circular, and may be designed for either flow-through or batch operation.

Cells used by the Chemiekombinat Bitterfeld in the German Democratic Republic [6, p. 749] (see Fig. 6), for example, have a volume of about 4 m^3, are circular in shape, and are equipped with a built-in mechanical agitator. The electrode system is monopolar. These batch-operated cells use unfiltered electrolyte; the resulting $KMnO_4$ is allowed to crystallize within the cells and is drawn off periodically through a bottom valve. The crude product must be recrystallized to separate it from residual ore gangue.

Figure 6. Electrolytic cell used in the Bitterfeld (GDR) process for the production of potassium permanganate
A) Vertical section; B) Cross sectiona) Anode; b) Cathode; c) Rubber-lined cell trough; d) Agitator; e) Bottom discharge valve; f) Agitator shaft; g) Spiral agitator

In the cell developed by the Carus Chemical Company, numerous bipolar electrodes are combined in an arrangement resembling a filter press to form a closed, diaphragmless, flow-through electrolyzer (Fig. 7) [46–48]. The anodic side of each cell sheet consists of Monel Metal screens, while the effective cathode area consists of a multitude of small steel protrusions. The rest of the cathode is covered with a corrosion-resistant

insulating material. A lower surface area for the cathode than for the anode maximizes the anodic oxidation of MnO_4^{2-} and minimizes undesirable cathodic reduction of both manganate and permanganate. The resulting potassium permanganate is crystallized outside the Carus cell in a continuous crystallizer system.

Crystallization. Crystallization of potassium permanganate is effected either directly in a specially designed electrolytic cell or in separate crystallizers. Modern installations use single- or multistage vacuum crystallizers, which produce a crystalline product directly from the mother liquor in such purity that only centrifugation and drying are required before the $KMnO_4$ is packaged and sold (see Fig. 8).

Removal of Impurities and Recycling. When the crude manganate is leached with dilute KOH a solid residue remains. This is composed of the insoluble portion of the ore gangue (e.g., iron oxide hydrates, precipitated aluminum silicate), unreacted MnO_2 ore, and some precipitated MnO_2 (from disproportionation of K_2MnO_4). These insoluble constituents are removed by the use of thickeners, vacuum filters, or filter presses. The Bitterfeld process operates with unfiltered electrolyte, but here the electrolyzers have been specially designed to cope with suspended matter.

In order to recycle potassium hydroxide generated in the electrolysis step (Eq. 4 in Section 4.2.2.2), the spent mother liquor is first concentrated by evaporation to a relative density of ca. 1.575 – 1.585. This "recovered" caustic potash is then recycled to the front end of the process and added to either the roaster or the liquid-phase oxidizer. Alternatively, after removal of dissolved impurities, the recovered KOH can be treated with carbon dioxide to produce potassium carbonate. This method has the drawback that there is a limited market for the substantial quantities of potassium carbonate coproduct.

Dissolved impurities (in particular silicate and aluminate from the gangue portion of the ore) must be removed from the process liquors in order to avoid formation of rock-like deposits on pipeline and equipment walls. Equally undesirable is the buildup of carbonate in the process liquors due to reaction of atmospheric CO_2 with KOH. Excessive carbonate concentrations in the recycle system reduce the rate of conversion of ore into manganates and can also cause low current efficiencies in the electrolytic cell.

All three major impurities (Si, Al, and carbonate) can be removed together with such minor impurities as Cu, Pb, Ni, and Co by treatment with calcium hydroxide [49]. Effective causticization of the potassium carbonate occurs according to

$$K_2CO_3 + Ca(OH)_2 \rightleftharpoons 2\,KOH + CaCO_3$$

and requires that the potassium hydroxide concentration be kept ≤ 80 g/L. The process used by Nippon Chemical Industrial Company [50] entails addition of $Ca(OH)_2$ as early as the roasting step to prevent formation of soluble carbonate and the solubilization of other impurities.

Waste Disposal. The treatment and disposal of solid wastes from permanganate production is an ecological as well as an economic problem. The waste product contains not only unreacted ore but also some precipitated MnO_2. The main constituents are derived from the insoluble portion of the ore gangue (Fe, Si, Al compounds) but these are accompanied by significant quantities of potassium and calcium salts. One permanganate producer has proposed recovering most of the adsorbed and chemically-bound potassium by treatment with calcium hydroxide. After washing, the treated waste could then be deposited in landfills [51]. The patent literature describes a number of potential uses for the waste from permanganate production, including extraction of residual manganese, or use of the waste as an absorbent for air pollutants [52], as a micronutrient additive for fertilizers [53], or in building materials [54].

4.2.2.3. Production Plants

This section gives a brief review of production plants for potassium permanganate in eight countries. Most of the reported production capacities are estimates.

India. Permanganate production began in India after World War II. Only one plant remains, that of Curti Chemicals (Goa) built in 1970 with a capacity of less than 1000 t/a. It uses a roasting step followed by electrolytic oxidation.

Figure 7. Carus Chemical electrolytic cell for the production of potassium permanganate from potassium manganate (VI) [47] A) Schematic overview of the cell bank; B) Side elevation of an individual cell section; C) Cross section of the anode side of a bipolar electrode; D) Cross section of the cathode side of a bipolar electrode a) Individual bipolar electrode; b) Anode (wire screen of Monel Metal); c) Base steel sheet; d) Steel cathode with perpendicular projections; e) Insulating plastic; f) Insulating spacer; g) Cutout for flow dividers; h) Cathode projections embedded in plastic; i) Flow dividers

Spain. The Spanish permanganate plant in Trubia was established in 1940 and modernized in 1977. The plant is operated by Asturquimica and capacity is 4000 t/a. A modified spray drier is used as the reactor in the first roasting step and a "plate" reactor for the second roasting step [55]. Electrolytic oxidation and vacuum crystallization occur continuously.

Japan. Nippon Chemical constructed a new, continuously operating plant in Aichi Prefectur in 1971 (capacity ca. 3000 t/a). An improved roasting process is employed for making the manganate intermediate, whereby the MnO_2–KOH reaction mixture containing hydrated lime is dewatered in a separate step before it is introduced into the two-stage roaster system [50]. The electrolysis cells are arranged in cascade fashion and overflow from the final stage is passed to a vacuum crystallizer.

Former Soviet Union. The Soviet Union operates three plants, built in the late 1950 s and early 1960 s. The plant in Rustavi has a capacity of 500 t/a and employs single-step anodic oxidation of ferromanganese [45, p. 875]. The second plant, in Saki, has a capacity of about 2500 t/a and uses technology similar to that of the Bitterfeld plant in the GDR. The third plant is also in Saki and has a capacity of about 3000 t/a. It uses discontinuous liquid-phase oxidation in the manganate step [45, p. 870], followed by batch electrolysis and crystallization.

Former Czechoslovakia. The Czech plant (Spolek pro Chimickou a Hutni Vyrobu n.p., Usti n.L.) was built in the 19 th century. It uses a two-stage roasting process with rotary hearth furnaces for the manganate step. Conversion of each batch of MnO_2 to K_2MnO_4 requires ca.

Figure 8. Production of potassium permanganate: continuous electrolyzing – crystallizing system

48 h. The monopolar, continuously operating electrolytic cells contain asbestos diaphragms and electrodes. Plant capacity in 1981 was stated to be 2000 t/a [56].

People's Republic of China. China, with ten state-owned plants, has become a major factor in the world permanganate market, especially as an exporter. Estimates of production capacity range from 7000 – 15 000 t/a. The largest most modern installation (with production of ca. 3000 t/a), established in 1954 in Guangzhou, Canton, presumably uses a liquid-phase oxidation process in the manganate step. The other (smaller) plants are said to employ roasting methods.

United States. The Carus Chemical Company of La Salle, Illinois, has been a producer of potassium permanganate since 1915. New production technology was developed and installed during the late 1950 s and early 1960 s when patented processes included liquid-phase oxidation in the manganate step [42–44] and closed bipolar cells with continuous crystallization in the permanganate step [46–48]. Numerous improvements have since been introduced, and the current process is fully continuous, highly automated, and in full compliance with environmental regulations. Production capacity is ca. 15 000 t/a.

4.2.3. Commercial Grades, Packaging, and Transportation

Potassium permanganate is offered in several standard grades, including technical, technical free-flowing, U.S.P., and reagent. Guaranteed assays for the various products range from 97 % $KMnO_4$ for the free-flowing grade (which contains an anticaking additive) to 98 % for the technical grade and 99 % for both U.S.P. and reagent grades (typical assays are usually approximately 0.5 % above the guaranteed levels). In addition to assay requirements, reagent grade and U.S.P. grade potassium permanganate conform to specifications set forth in the U.S.P. [57] and the 7 th Edition of Reagent Chemicals [58], respectively. Additional specialty grades are also available.

Material intended for drinking water treatment must conform, for example, to NSF Standard 60 [59] in the United States and to DIN 19 619 [60] in the Federal Republic of Germany. Packaging is in steel drums or, for large users, bulk containers, bulk cars, and trucks.

The following transportation regulations are applicable: IMDG code D 5187, class 5; RID/ADR class 5.1, number 9 c; UN no. 1490; CFR 49: 172.101 oxidizing material.

4.2.4. Uses

The United States is the leading consumer (followed by Western Europe and Japan) of permanganate intended for environmental applications, such as drinking water treatment (removal of tastes, odors, iron, and manganese [61]; control of trihalomethanes [62]); wastewater treatment (destruction of hydrogen sulfide [63] and other toxic and/or corrosive compounds, including phenols [64] and plating wastes [65]); and air purification (degradation of malodorous or toxic constituents in industrial off-gases) [66].

In other parts of the world (particularly Eastern Europe and India), the principal use of potassium permanganate is in chemical processing, especially the manufacture of synthetic organics (e.g., saccharine, chloroamphenicol, ascorbic acid, isonicotinic acid, pyrazinoic acid). Even in the Western world, chemical processing applications are significant. Thus, numerous intermediates for pharmaceuticals and pesticides are made via permanganate oxidation, as are many fine organics, including flavoring. Significant tonnages are also consumed for the oxidative destruction or precipitation of undesirable impurities, often ones that impart unwanted colors or odors. $KMnO_4$ is used in the purification of such chemicals as methanol, ethanol, acetic acid, caprolactam, adiponitrile, plasticizers, carbon dioxide for dry ice manufacture, zinc chloride, and hydrofluoric acid. In recent years, $KMnO_4$ has played a major role in the bleaching of indigo and other dyes for cotton twill fashion garments. This involves processes known as "frosting", "icing", or "acid washing". Permanganate is also used for bleaching beeswax, natural sponges, jute fibers, and certain clays.

Other important uses include surface treatment of carbon steels and stainless steels (descaling and desmutting, especially in wire manufacture), etching of rubber and plastics, and decontamination of nuclear reactors. Fish farmers utilize $KMnO_4$ to prevent oxygen depletion and to control fish parasites.

4.2.5. Economic Aspects

Even though potassium permanganate is not a large-volume chemical it is industrially very important. Especially in the manufacture of specific organic intermediates (Section 4.2.4) $KMnO_4$ is an indispensable oxidant.

World production capacity for potassium permanganate is estimated to be 43 000 – 51 000 t/a, although actual demand is less than 30 000 t/a. Most of the idle capacity is to be found in countries with free market economies: the United States, Western Europe, and Japan. Two of the three West European permanganate plants have been shut down since 1975: Rhône Poulenc's installation in France and the Boots Company plant in the United Kingdom.

Much of the permanganate output from countries with controlled economies enters Western markets at very low prices as a result of extremely low labor costs and virtually no environmental overhead. Government-imposed antidumping duties provide some relief, but not enough to ensure competition on a comparable-cost basis between the imported and domestic product.

4.3. Sodium Permanganate

Many permanganates other than $KMnO_4$ are known [44, pp. 859 – 860], but only sodium permanganate is currently of industrial significance. $NaMnO_4 \cdot H_2O$ [*10101-50-5*], M_r 195.93, ϱ 1.972 g/cm^3, *mp* 36.0 °C, can be made in several ways, including anodic oxidation of ferromanganese in Na_2CO_3 solution [6, p. 759], via aluminum permanganate [67], or from $KMnO_4$ by the hexafluorosilicate method [68]. The price of sodium permanganate is about 5 to 8 times that of $KMnO_4$. This is mainly due to the fact that $NaMnO_4$ cannot be made in the same way as $KMnO_4$, because the oxidation of MnO_2 in a NaOH melt does not lead to the required Na_2MnO_4 (with hexavalent Mn) but only to

Na_3MnO_4 with pentavalent Mn. The latter is very unstable in dilute NaOH solution (and therefore cannot be converted electrolytically to the desired $NaMnO_4$). Even if electrolytic oxidation were possible, there would still be the difficult problem of isolating the extremely soluble $NaMnO_4$ from the alkaline mother liquor.

Sodium permanganate is readily soluble in water (900 g/L at ambient temperature) and is preferred for applications requiring high concentrations of the MnO_4^- ion. Thus, $NaMnO_4$ is used in the etching of plastic parts such as printed circuit boards [69], as well as in some special organic oxidation reactions, particularly if the presence of potassium ions is undesirable.

5. Miscellaneous Manganese Compounds

Manganese(III) fluoride [*7783-53-1*], MnF_3, M_r 111.93, ϱ 3.54 g/cm^3, is a red crystalline material, thermally stable to 600 °C, that is obtained by reacting Mn(II) halides with elemental fluorine at 200 °C. It decomposes in water and is used as a fluorinating agent for organic compounds.

Manganese hypophosphite [*10043-84-2*], $Mn(H_2PO_2)_2 \cdot H_2O$, M_r 202.91, is soluble in water, forms pink, odorless crystals, and decomposes spontaneously upon heating to flammable phosphine. It is prepared from calcium hypophosphite and manganese sulfate. The compound is used as a stabilizer to improve the heat and light resistance of certain man-made fibers and as a food additive and dietary supplement.

Manganese(III) acetylacetonate [*14284-89-0*], $Mn(C_5H_7O_2)_3$, *mp* 172 °C, is a brown to black crystalline solid that is insoluble in water but soluble in organic solvents. In the dry state it is relatively stable. It is synthesized by reacting manganese(III) sulfate, acetylacetone, and ammonia in an aqueous medium, and is used industrially as a catalyst for organic reactions (e.g., in the polymerization of 2-hydroxyethyl methacrylate to a soluble polymer [70]).

Manganese ethylenebis(dithiocarbamate) [*12427-38-2*], Maneb, $(CH_2NHCS_2)_2Mn$, M_r 265.3, is a yellow powder. It is prepared by the addition of an aqueous solution of ethylene diamine and ammonia to carbon disulfide, followed by neutralization with acetic acid and precipitation with $MnSO_4$ or $MnCl_2$. The compound is an important fungicide (→ Fungicides, Agricultural).

Methylcyclopentadienylmanganese tricarbonyl [*12108-13-3*] (MMT), M_r 218.08, ϱ 1.39 g/cm^3, *bp* 233 °C, is a yellow liquid that is insoluble in water but soluble in organic solvents. Several synthetic routes exist for this compound. For example, manganese(II) chloride may be allowed to react with cyclopentadienylmagnesium bromide, C_5H_4MgBr, to form biscyclopentadienylmanganese, an intermediate that reacts with carbon monoxide to give the tricarbonyl. This is then methylated in the presence of Friedel–Crafts catalysts. The product finds limited use as an antiknock additive in motor fuels and as a combustion aid in heating oils.

6. Occupational Health and Environmental Aspects

Manganese plays an important biochemical role in animal and plant life, and is regarded as an essential trace element [71]. It is added as a fertilizer (in the form of MnO or $MnSO_4$) to manganese-deficient soils and is also a constituent in dietary supplements for animals and humans.

The United States Food and Drug Administration has given GRAS (**G**enerally **r**ecognized **a**s **s**afe) clearance to manganese chloride, manganese citrate, manganese gluconate, and manganese sulfate as direct human food ingredients [72]. Nevertheless, excessive intake and long-term exposure, especially to airborne manganese, can lead to toxic effects [73–76]. Acute poisoning with manganese compounds in humans is very rare, but a few cases involving potassium permanganate are mentioned in the literature, either in connection with its attempted use as an aborticide (abortifacient) or in cases of attempted suicide. The human LDLo for $KMnO_4$ is reported to be 143 mg/kg, with a TDLo for women of 2400 mg kg^{-1} d^{-1} [77].

Chronic manganese poisoning is of much greater concern [78]. Inhalation of manganese in the form of oxidic dust or as vaporized metal over extended periods of time (3 months to several years) increases susceptibility of the res-

piratory organs to infection (manganese pneumonia). Manganese can also cause permanent damage to the central nervous system (manganism). The hazard of chronic manganese poisoning affects not only workers in manganese mines and manganese ore crushing/grinding facilities but also those employed in various manganese-consuming industries (e.g., the production and use of ferro- and silicomanganese in steelmaking, welding with manganese-containing welding rods, dry cell manufacture, and production of manganese chemicals) [79], [80]. The early symptoms of manganism are classed as psychological disturbances: fatigue, loss of appetite, incoordination, speech disorders, and psychotic behavior. Manganism at this stage is reversible provided exposure ceases. Continued exposure causes the disease to enter a second stage, in which permanent injury is inflicted on the central nervous system. Symptoms include severe rigidity of the limbs with jerky movements, gait problems, tremors, and excessive salivation and perspiration. There is some similarity between the symptoms of manganism and those of Parkinson's disease.

In the United States, the Federal Republic of Germany, Switzerland, and Japan a general ceiling value (MAK) has been set for manganese in air at 0.5 mg/m^3/BAT-Wert: 20 mg/l[87]. The ceiling value for Mn_3O_4 is 1 mg/m^3 [81]. OSHA has proposed lowering the "Permissible Exposure Limit" to manganese at the workplace to 1 mg/m^3 [82]. On the other hand, the United States Environmental Protection Agency decided not to designate manganese as a hazardous air pollutant under the Clean Air Act, mainly because public exposure to manganese is far below levels associated with serious noncarcinogenic health effects, and available data do not indicate that manganese is carcinogenic [83].

Detailed information about the location of major manganese air emission sources in the United States can be found in [84]. At current exposure levels, manganese does not constitute a general environmental risk [81]. The limit for manganese in drinking water in the United States and most West European countries is 0.05 ppm. This low value is based largely on aesthetic rather than toxicological considerations [85].

1. History

The term "margarine" was coined by the French chemist Michel Chevreul in 1814. He used it to describe one of what he thought to be the three primary constituents of natural fats, the others being *oleine* (from the Latin *oleum* for oil) and *stearine* (solid fat, from the Greek *stear* for tallow). "Margarine" was supposedly a third, semisolid constituent, so-named (from the Greek *margaron*, pearl) because of its pearl-like, crystalline appearance. Chevreul believed that these three substances were glycerides of the fatty acids oleic acid, stearic acid, and margaric acid, respectively. Subsequent investigation has shown that natural fats contain many more fatty acids than these three (→ Fats and Fatty Oils, Chap. 2.). Oleic acid and stearic acid have since acquired unique chemical identities, and some authors still use Chevreul's "margaric acid" as a trivial name for heptadecanoic acid even though his original concept has been shown to be erroneous. The terms olein and stearin have been retained to describe the lower and higher melting fractions into which natural fats can be separated, but the term margarine is no longer employed in that context. It is now used instead to describe a commodity resembling butter but manufactured from fats derived from sources other than milk (→ Dairy Products, Imitation).

Such a commodity was first produced by Hippolyte Mège – Mouries in 1869 in response to a prize offered by Napoleon III for a substitute for butter. Mège – Mouries removed the stearin from beef tallow by fractional crystallization, leaving a mixture of olein and margarine or *oleomargarine*. This he emulsified with milk, water, and a little alkali to produce a plastic, fat-continuous emulsion resembling butter in texture. The term oleomargarine (or "oleo") is still used for this product in the United States. In Europe the name was shortened to margarine, a name that was established by Act of Parliament as the legal term in Britain in 1887 in preference to the suggested alternative "butterine".

Early production of margarine was dependent upon the availability of the oleomargarine from beef tallow to provide the desired consistency. However, two inventions soon opened the way to a wide range of natural fats as potential raw

materials for margarine manufacture: *hardening* and *interesterification*.

Hardening, or hydrogenation, consists of reactions of unsaturated fats with hydrogen, thereby raising their melting points and in some cases increasing their oxidative stability. This procedure was introduced by NORMANN in 1903 [4].

Interesterification involves the exchange of fatty acid moieties between or within glycerides to create new glyceride components. The exchange of acid moieties between esters had been demonstrated by FRIEDEL and CRAFTS [5] as early as 1865, and its potential application to natural fats was demonstrated by NORMANN in the 1920s [6]. Because of the required high temperatures (> 200 °C) and long reaction times (several hours), however, the process was of no interest to margarine manufacturers until ECKEY introduced alkali-metal catalysts in 1948 [7]. The original conditions are not only economically prohibitive, they are also deleterious with respect to the fat. Using alkali-metal catalysts the reaction can be carried to completion below 60 °C within minutes.

A third major development in the manufacture of margarine was the introduction of the votator system in 1936, permitting the ingredients (i.e., fat, the aqueous phase, and minor components) to be premixed and then subjected to simultaneous rapid shearing and cooling. This not only causes the aqueous phase to be finely and uniformly dispersed throughout the fat phase but also gives the processor a greater degree of control over the final texture of the product.

Margarine was first conceived as a substitute for butter, and from the start it was seen as a commercial threat by the dairy industry. Margarine manufacture was soon controlled by legislation designed to protect the dairy interest. Suppression of the name "butterine" was considered to be an early victory for the dairy farmers in this long standing "war". Other legislation soon decreed that margarine must be sold as a product distinct from butter, and it prohibited the extending of butter products by incorporation of small proportions of margarine. In the United States, the addition of color to margarine to give it a more butter-like appearance was long prohibited, and manufacturers had to resort to including capsules of color with the packs of margarine, which consumers could blend in to their own satisfaction.

Despite such legislation, the relative cheapness of margarine soon made it a major component of the diet, especially for the poorer members of society, and enlightened governments quickly foresaw the dangers of malnutrition if nutritional standards were not laid down and maintained. The proportion of water was thus controlled at no more than 15 % in most countries, and the addition of vitamins A and D was made compulsory in order to maintain margarine at a nutritional standard comparable with that of butter.

Recent technical advances and new insights into nutrition and health have enabled margarine manufacturers to exploit more fully the flexibility inherent in the formulation of margarine. As a result, margarine is now a product in its own right, not simply a cheap substitute for butter. For example, wider usage of domestic refrigerators has produced a demand for products plastic enough to spread at low temperatures, a demand that has been met by the so-called *soft blend margarines*. These contain fats chosen in such a way that the product retains a spreadable plasticity over a wide range of temperatures. A high level of fat in the diet, especially saturated fat, is now considered undesirable, and this has led to the development of *low-fat spreads* and to the use of *fat blends* with a high proportion of polyunsaturated fatty acids (PUFA). The early protective legislation has also come under pressure from responsible nutritional authorities, who have urged that margarine manufacturers be permitted more flexibility. Consumers now have a wide choice of margarine-type products, covering the whole gamut of fat contents from conventional margarine at 85 % down to very low fat spreads at ca. 20 %, and including various melanges with dairy products such as *low calorie and high PUFA "butters"*.

Brand names for the various types of margarine are listed in Table 1.

2. Properties of Margarine

The properties of margarine can be considered under two headings:

Table 1. Some typical margarines and other spreads with brand names in use at the time of writing (1989)

Fat content, wt%	Brand name	Manufacturer	Country

1) *Subjective properties* that are assessed by the reaction of a consumer when presented with a sample of the margarine
2) *Objective properties* measured with laboratory instruments

2.1. Subjective Properties

The most obvious subjective property is *appearance,* which comes into play as soon as the consumer opens the package. First, the product must have an attractive color. This has traditionally meant a yellow color similar to that of butter. Margarine must also have a *smooth, creamy-looking texture*; i.e., it should not appear grainy or greasy. When the consumer applies the margarine to a piece of bread or biscuit, it should have good "spreadability"; i.e., it should be soft enough to spread smoothly and easily without breaking into lumps, exuding water, or dragging the bread surface. Furthermore, the margarine must have an acceptable flavor and "mouthfeel".

For Europe and many other parts of the world the standard for good *flavor* is fresh butter, and much research has been devoted to creating flavor cocktails imparting a butter-like taste. In some places, however, other flavors are preferred. Thus, in parts of South America fruit flavors such as pineapple are appreciated, while in some African countries fish flavors are popular.

Mouthfeel is a reflection of the physical changes that take place as margarine melts and breaks down under the action of teeth and tongue and mixes with saliva in the warm environs of the

mouth. This melt-down can take place smoothly or lumpily. The melt-down may be complete, or some unmelted fat may remain and be perceived as a waxy coating around the tongue and palate. The melted product can feel creamy or thin and watery. In some circumstances, a cool sensation is perceived, perhaps due to a rapidly melting fat blend. The flavor release pattern is also affected by the way in which margarine breaks down, releasing flavor components to the palate at different rates, which may in turn influence the consumer's overall perception of flavor.

All these effects can be related, in theory at least, to such physical properties of the margarine as melting characteristics or emulsion stability, but it is not possible to measure all of them directly with laboratory instruments.

2.2. Objective Properties

2.2.1. Color

The color of margarine is defined in terms of the tristimulus concept, which postulates that any color can be specified in terms of the three primary colors red, yellow, and blue. In practice, the color of light reflected from the surface of a margarine sample is matched against that of light which has passed through a series of filters based on the primary colors. The color is then defined in terms of the density of each of the filter colors required to give a match. A suitable commercial instrument for this purpose is the Lovibond Tintometer [8].

Color is primarily dependent on the amount of coloring material added to the margarine mixture, but it is also affected by the physical nature of the margarine (e.g., by the ratio of solid fat to liquid oil in the fat phase, the amount of the water phase, and the size and distribution of water droplets).

2.2.2. Gloss

Gloss is a measure of the efficiency with which light is reflected from the surface of the margarine. A mirror surface reflects a beam of light at the same angle at which the beam strikes the surface, with little or no scattering. A matt surface scatters the beam so that the intensity of the reflected light is uniform over a wide angle of reflection. A glossy surface falls between these two extremes: a portion of the light is reflected along the angle of incidence, but some is scattered. Glossiness can therefore be measured by comparing the intensity of incident light with that of reflected light at predetermined angles.

Like color, gloss is dependent upon the physical nature of the margarine; i.e., upon the proportion and distribution of solid fat crystals and water droplets.

2.2.3. Melting Properties

The melting characteristics of a margarine are essentially those of the fat blend used in its composition, and they are responsible for many of the product's subjective characteristics (see Section 2.1). A fat blend, and indeed a natural fat, consists of a complex mixture of glycerides, each with its own characteristic melting point and each influencing and influenced by the melting of other glycerides in the mixture through the formation of solutions and eutectics. As a result, a solid fat does not show a single sharp melting point, but rather a gradual softening over a wide range of temperature. The melting character of a fat must therefore be defined in terms of the solids content of the fat at a given temperature.

Dilatation. Traditionally, solids content was measured by dilatation [9]. A completely solid fat, like any other solid, shows a small increase of volume with increasing temperature. A fully liquid oil also expands when heated, slightly more than does a solid fat. However, when the solid melts to a liquid, a considerably greater volume change is observed. Therefore, the increase in volume in the course of heating between two temperatures is essentially a measure of the proportion of the sample that melts over that temperature range. In practice the change is measured with a dilatometer, which consists of a glass bulb containing the fat sample connected to a graduated capillary tube containing a marker liquid. As the volume of fat in the bulb increases the marker liquid is pushed up the capillary, permitting the volume change to be quantified. Such a bulb is immersed sequentially in a series of water baths at different temperatures and for each bath the level of liquid in the capillary is noted.

After correcting for expansion of the glass and the liquid oil it is then possible to calculate the proportion of fat melted at each temperature.

Nuclear Magnetic Resonance. Today it is generally more convenient to use a nuclear magnetic resonance (NMR) technique to measure solid fat content [10]. This is possible because a proton within a molecule responds differently to a strong magnetic field depending on whether it is held rigidly in a solid crystal matrix or only restrained in a liquid substrate. NMR instruments especially designed for this application are commercially available.

Polymorphism. One factor that can confuse the measurement of solid fat content by either dilatation or NMR is the phenomenon of polymorphism [11]. Thus, many compounds are capable of assuming any of a number of different physical forms, each with a different melting point. This phenomenon is especially evident in the behavior of fats. When a melted fat is cooled rapidly below its melting range, it usually crystallizes in an unstable form known as the α modification. On standing, this rearranges into a more stable β or β' form (cf. Section 3.1.1). Stable modifications can also be achieved by slow cooling or by crystallization from a solvent. The solid content of a particular sample depends on the relative proportions of these various polymorphs and therefore on the way in which the sample has been prepared. For quantitative comparisons, samples must therefore be subjected to a standard regime before their solids content is measured.

2.2.4. Penetration

Penetration is a measure of the resistance shown to a plunger pressed through the margarine under standard conditions. It depends upon both the viscosity of the liquid components of the margarine mix and the rigidity and extension of the network of solid fat crystals (see Section 3.1.1). Penetration is measured with a penetrometer [12]. A plunger with a standard conical tip and loaded with a standard weight is allowed to sink for a standard period of time and by gravitational force alone into the surface of the margarine. The depth to which the plunger penetrates is recorded on a dial. Such an instrument must normally be housed in a temperature-controlled environment, and the sample should be stored under controlled temperature conditions for at least a week prior to measurement.

The penetration value can be indirectly related to such subjective properties as spreadability and how the margarine feels when cut with a knife. It also gives an indication of how well the margarine will retain its shape during packing, storage, and transport.

2.2.5. Drop Size

The aqueous phase of a margarine is dispersed in the fat phase in the form of small droplets with a maximum diameter of about 100 µm. Average droplet size is 5 – 10 µm. In conventional margarines, drop size is an important factor in controlling the biological stability of the product. Most microorganisms can only develop in an aqueous environment and their growth throughout the product is therefore inhibited if water is present only in very small drops. In the case of low-fat spreads (where water constitutes 60 % or more of the total composition) the droplet size can also affect such subjective properties as hardness, mouthfeel and flavor release, but these considerations are less critical in conventional margarines (with only ca. 15 % water content).

Drop size can be measured directly with an optical microscope or indirectly by NMR techniques [13]. Both methods are subject to difficulties of interpretation because the droplets in a given sample have a range of sizes and are not necessarily spherical.

2.2.6. Salt Release

The salt release test provides an indication of how margarine is likely to break down in the mouth. Thus, a sample of margarine is transferred to a vessel containing water and two electrodes with which the conductivity of the water can be measured. The sample is then stirred and the temperature is slowly raised. When the sample begins to break down, the aqueous phase of the margarine is released from its surrounding fat phase and any salt present is liberated. As a result, the conductivity of the water increases.

For a good product this increase should occur at around mouth temperature, i.e., 33 – 37 °C. If the salt release occurs at a considerably higher temperature (e.g., 40 °C) then the product will have a dead, waxy feel in the mouth.

2.2.7. Keeping Properties

If stored for too long or under unfavorable conditions, desirable margarine properties may be lost or undesirable ones may develop. Physical, chemical, or biological changes may be responsible.

Physical Changes. Physical changes lead to a breakdown in the structure of the margarine.

1) *Emulsion instability* results in the coalescence of dispersed water droplets and visible separation of water from the product. Provided a suitable emulsifier has been chosen and the product has been correctly processed, this only becomes a problem if the product is subjected to extreme changes of temperature.
2) *Oily exudation* indicates a breakdown of the crystal network in the fat phase of the product, and there is visible separation of liquid oil at the surface (i.e., between the paper and the product in a wrapped margarine, or between the walls of the tub and the product in a tub-filled margarine). Exudation may arise as a result of inappropriate choice of fat composition, but in an established product it is more often an effect of exposure to extreme temperatures or to mechanical mishandling.
3) *Sandiness or graininess* is due either to continued growth of individual crystals or to aggregation of crystals after processing. The effect can be detected visually (by an excessively matt or granular surface appearance) or by mouthfeel [14]. Certain fats or fat blends (notably those containing palm oil and lard) are particularly prone to this fault due to the presence of large quantities of single species of glycerides, oleodipalmitins, or palmitodioleins, which readily form compound crystals. Critical proportions of these fats should be avoided. Interesterification can also be used to reduce the concentration of individual triglycerides responsible for the effect.

Chemical Changes. Chemical changes affect the flavor of a product, causing rancidity through either autoxidation or hydrolysis.

Autoxidation refers to reaction between fatty acid chains and atmospheric oxygen. The first step is removal of a hydrogen atom from the hydrocarbon chain of the fatty acid and its replacement by a hydroperoxide group. The latter then reacts further by addition to double bonds or by chain cleavage to give a complex mixture of aldehydes, ketones, and short-chain fatty acids. Many of these products are highly flavor-intensive, only a few parts per million being sufficient to impart a detectable flavor. Hydrogen atoms on carbon atoms adjacent to double bonds, and to a lesser extent those adjacent to ester groups, are most labile and therefore most readily attacked. Polyunsaturated fatty acids are more susceptible than monounsaturated acids, which in turn are more susceptible than saturated acids. Fish oils are highly unsaturated, with up to six double bonds per fatty acid chain, and these are particularly prone to autoxidation. They have the added disadvantage that their autoxidation products have characteristic rancid, fishy flavors unacceptable in a margarine product. For this reason fish oils are only used in margarine formulations after the number of double bonds has been reduced by hardening.

In general, autoxidation can be controlled by efficient refining (see Section 3.1.1). Refining not only removes indigenous flavors from natural oils or fats but also reduces the level of any pro-oxidants present. If a blend contains predominantly animal fats, further protection by antioxidants may be required. This precaution is not normally necessary for vegetable fats and oils, as these contain adequate quantities of natural antioxidants in the form of tocopherols.

Hydrolytic rancidity occurs when the ester linkage joining the fatty acid moiety to glycerol is split, leading to the release of free fatty acid. This can be a result of autoxidation, but it is more likely to be caused by hydrolysis. Long-chain fatty acids ($\geq C_{16}$) are virtually flavorless, so their release does not produce a flavor problem. On the other hand, short-chain fatty acids ($\leq C_{12}$) have quite intense intrinsic flavors, and their release causes the off-flavors variously described as rancid, soapy, or cheesey. Since butter contains a relatively high proportion of such

short-chain acids it is more prone than most margarines to this form of off-flavor development.

Biological Changes. Biological changes are the result of microbial contamination of a margarine. If allowed to develop, microorganisms can render a product unsightly and unwholesome as well as subject to physical and chemical changes. The primary means of controlling microorganisms is strict attention to hygiene during storage of ingredients, processing, and packaging, but preservatives are sometimes used to protect the stored product after packaging. Because of their high water content, low-fat spreads are more susceptible than conventional margarines to this type of deterioration.

3. Composition

All margarines consist of both a fat phase and an aqueous phase. In conventional margarines the fat phase constitutes ca. 85 % of the total mixture. Low-fat spreads can contain as little as 20 % fat phase, with a correspondingly larger amount of aqueous phase.

3.1. The Fat Phase

The fat phase consists predominantly of blends of natural or modified oils or fats. These comprise not only triglycerides but also various minor natural ingredients such as tocopherols and sterols. Small amounts of other substances must be added by the manufacturer, including emulsifiers, coloring agents, and antioxidants.

3.1.1. Choice of Fat Blend Components

The most essential characteristic of the fat blend for a margarine is that it contains a certain proportion (at least 15 – 20 wt%) of a fat that is solid at normal ambient temperature. This solid fat is known as the *hardstock*, and its function is to form a network of fat crystals through the otherwise liquid oil and so give it a certain rigidity [15]. Ideally, the hardstock should all have melted or dissolved at mouth temperature, otherwise the product has a heavy, waxy mouthfeel. However, a small proportion (≤ 2 %) of higher-melting fats can be tolerated without the effect being too noticeable. Indeed, a little high-melting material can be beneficial, in that it promotes crystallization of the main fraction of the hardstock and also stabilizes the plasticity of the blend over a wide range of temperature. In margarines designed for sale in tropical countries, ideal mouthfeel may have to be sacrificed to some extent and the proportion of high-melting fat increased to ensure that the margarine withstands high ambient temperatures.

Crystallization characteristics of the hardstock can also be critical, but this is not usually a concern for general-purpose margarines (i.e., those other than soft blend or high PUFA margarines). Typical formulations are based on a mix of fats with a wide range of melting points. The fats are typically hardened or partially hardened to ensure a substantial proportion of solid fat over a wide temperature range. An excessively high level of high-melting components must be avoided, as must components with undesirable crystallization characteristics. An example of such a characteristic is the tendency to crystallize slowly, causing too much growth of solid crystals subsequent to mechanical processing. This phenomenon, known as *posthardening*, gives rise to products with a hard, brittle texture and is especially associated with palm oil. The somewhat similar problem of sandiness or graininess is commonly associated with lard or blends of lard and palm oil.

Apart from these restrictions, the main criterion for choice of fat components is the cost, and the blend formulator will adapt his formulations to whatever is economically attractive at the time. He is aided in this by the concept of linear programming, which postulates that the melting characteristics of a blend of fats are additive functions of the individual components of the blend [16]. Thus, the solid fat content of a blend S can be calculated from the formula:

$$S = xA + yB + zC + \ldots$$

where $x, y, z, \ldots$ are the proportions of the individual components and $A, B, C, \ldots$ are the solid fat contents of those components. This formula is reasonably valid over a wide range of blends and conditions, and enables the blender to substitute components at will depending on availability and cost. For soft blend margarines, and

especially for high PUFA margarines, the crystallization characteristics of the hardstocks are more critical. In order to comply with physical or nutritional requirements, the proportion of hardstock must be kept to a minimum and the ability of the hardstock to form an intermeshing crystal network must be maximized. This means that fats with a tendency to crystallize in the β form, which exhibits small, compact, spherulitic crystals with little intercrystal interaction, are rejected in favor of those with a tendency to form β' crystals, with extended open dendritic growth (→ Fats and Fatty Oils, Chap. 3.).

Typical Oils and Fats Used in Margarine. The oil blender can select his components from a wide range of natural oils and fats but only about a dozen are of commercial importance at any one time (Table 2). The list varies depending on agricultural practice and availability, but the following applies at the time of writing (1989). Of the liquid oils, soybean oil [*8001-22-7*] is the most widely used, with rapeseed oil [*8002-13-9*] a close equivalent in Europe. Sunflower oil [*8001-21-6*] is favored in high PUFA blends because of its high content of linoleic acid (ca. 50 – 60 %) and the absence of the linolenic acid present in soybean oil, which reduces flavor stability. Safflower oil [*8001-23-8*] is more expensive than sunflower oil, but it is favored by some manufacturers because it has an even higher linoleic acid content and can therefore be used to maintain a high PUFA content with a higher level of hardstock. Peanut oil [*8002-03-7*] was at one time widely favored because of its high oxidative stability, but it is now more expensive than other liquid oils. Palm oil [*8002-75-3*] and lard [*61789-99-9*] are semiliquid oils whose usage in unmodified form is restricted by the crystallization characteristics discussed above. Apart from lard, the only animal fat to find wide application is beef tallow [*61789-97-7*] , but, as Mège – Mouries found (cf. Chap. 1), the high-melting stearin must be removed before beef tallow can be used. Butter fat is of course incorporated into melange products. The lauric fats (palm kernel oil [*8023-79-8*] and coconut oil [*8001-31-8*]), so called because they contain a high level of lauric acid, are also useful as hardstock components since they have relatively sharp melting points near mouth temperature. Marine oils are among the cheapest oils available, but because

Table 2. Typical oils used in margarine manufacture

Type of oil	Region of origin	Use*
Soybean	USA and South America	widely used as a cheap source of PUFA (linoleic acid) also, after hardening, as a hardstock
Cottonseed	USA and Eastern Mediterranean	in margarine mainly used after hardening as a hardstock especially in USA
Rapeseed	North America and Northern Europe	since the development of low-erucic varieties, this has been increasingly used as a replacement for soya bean oil in Europe and Canada
Sunflower	widely distributed in warmer temperature zones	main source of PUFA (linoleic acid)
Safflower	USA, Central America, North Africa, and India	richer in PUFA than sunflower but more expensive
Groundnut	widely distributed in semitropical areas	formerly one of the basic commodity oils for margarine, both as a liquid oil and, after hardening, as a hardstock but now relatively expensive
Palm	Malaysia and Central Africa	widely used both as the whole oil and after fractionation or interesterification when melting characteristics are important
Lard	widely distributed where pigs are raised, mainly USA and Europe	used in similar contexts to palm oil but only in circumstances where the animal source is not important
Beef tallow	USA, Europe, and Australasia	limited use of the olein in margarines, especially those products where texture is more important than health appeal
Palm kernel	as for palm oil	widely used as a hardstock because of its relatively sharp melting range at about mouth temperature
Coconut	Pacific Islands, West Indies, and Southern Indian Continent	as for palm kernel
Fish		
Herring	North Atlantic South	very cheap source of oil but because of flavor problems can only be
Menhaden Pilchard Anchovy	Atlantic North Pacific South Pacific	used in food products after hardening; however, increased exploitation as source of essential fatty acids and sale as such through pharmacies and health food stores may alter this pattern of use

* PUFA = polyunsaturated fatty acids

of flavor problems they can only be used (after hardening) in cheaper, lower quality margarines. At one time this source was dominated by whale oil, but embargoes placed on whaling for conservation reasons have caused whale oil to be replaced by oils derived from such oily fish as herring, menhaden, and anchovy. For further information on the oils and fats described in this section, see → Fats and Fatty Oils.

3.1.2. Preparation of Fat Blends

3.1.2.1. Refining

All crude oils are darkly colored and strongly flavored, and they contain such undesirable components as free fatty acids and phosphatides. They must therefore be subjected to a refining process before use to produce a bland, lightly colored, neutral oil with increased resistance to autoxidation. Conventional refining involves three main stages: neutralization, bleaching, and deodorization (→ Fats and Fatty Oils, Chap. 6.).

Neutralization removes free fatty acids and it is carried out in the early stages of refining because acids would interfere with such later procedures as bleaching. In the alkali neutralization process, the crude oil is stirred with an aqueous solution of sodium hydroxide, which reacts with free fatty acids to form soaps. After settling, the aqueous phase containing the soaps is drained off. In the alternative physical refining process the oil is neutralized by distillation, free fatty acids being more volatile than the parent triglycerides.

Oils with a high proportion of phosphatides (e.g., soybean oil) are subjected to *degumming*, in which boiling water is used to hydrate and precipitate the phosphatides. Phosphoric or citric acid is often included in the boiling water to facilitate hydrolysis of the more resistant phosphatides.

The dried, neutralized oil is next subjected to *bleaching*. This process decolorizes the oil and removes various minor components, including compounds of heavy metals (especially iron and copper), which promote autoxidation, and of alkali metals, which promote hydrolysis. An absorbent material (usually an activated bleaching earth like fuller's earth, but sometimes charcoal) is stirred into the oil and stirring is continued under an inert atmosphere for 20 – 30 min at 80 – 120 °C, after which the absorbent is removed by filtration.

The final stage of refining is *deodorization.* The oil is heated to 180 – 250 °C for several hours while steam is blown through it. A vacuum is also applied to remove volatiles, which include flavor components (especially short-chain autoxidation products and residual free fatty acids).

In addition to simple refining, natural oils are sometimes subjected to procedures designed to alter their physical or chemical characteristics. Examples include hardening (hydrogenation), interesterification, and fractionation, which are discussed in the following sections.

3.1.2.2. Hardening

Hardening or hydrogenation is the process by which unsaturated fatty acids in an oil are reacted with hydrogen in the presence of a catalyst (→ Fats and Fatty Oils, Chap. 8.). Hydrogen adds to carbon – carbon double bonds in the fatty acid chain, converting them to saturated bonds.

The most common catalyst in oil and fat processing is activated metallic nickel, although other activated metals are sometimes used. Catalysts are most active when freshly prepared, and they lose activity with use, especially when subjected to oils containing a significant amount of sulfur. Sulfur is the most common poison for this type of catalyst. Some catalysts are deliberately poisoned with high-sulfur oil to achieve a specific degree of activity, because less active catalysts show greater selectivity.

Selective catalysts favor the hydrogenation of polyunsaturated fatty acids relative to monounsaturated fatty acids. Thus, conversion of linoleic acid, with two double bonds, to a form of oleic acid with only one double bond, is favored over the conversion of oleic acid to stearic acid with no double bonds. With a *nonselective catalyst* on the other hand, double bonds are attacked randomly; saturation of linoleic acid thus proceeds in parallel with that of oleic acid.

Another potential reaction under hardening conditions is isomerization without the addition of hydrogen. That is, the positions of double bonds along the chain may change. Moreover,

cis double bonds, which prevail in natural oils and fats, may be converted into the trans form, a geometry that occurs only rarely in natural oils. Isomerization reactions are favored by less active catalysts and also under conditions of hydrogen starvation.

The main purpose of hardening is to raise the solids content of an oil. In general, the more unsaturated the oil or fat, the lower is its melting point. Melting points of trans fatty acids are also higher than those of the corresponding cis isomers. Nonselective hardening tends to produce a wider mix of solid components, giving a fat that is plastic over a wide range of temperature. Selective hardening and trans hardening both favor a less complex mixture, resulting in a narrower melting range. Hardening also helps to stabilize a polyunsaturated oil against autoxidation. Thus, the linolenic acid in soybean oil (with three double bonds) is reduced in the course of hardening, as are the highly unsaturated fatty acids (with five or six double bonds) in fish oils.

3.1.2.3. Interesterification

Interesterification alters the ester links in oils and fats joining fatty acid moieties and glycerol; thus, one fatty acid residue from one of the three positions on glycerol is interchanged with another , either on the same molecule or on another molecule (→ Fats and Fatty Oils, Chap. 4.2., → Fats and Fatty Oils, Chap. 9.). This process commonly results in a random fatty acid distribution over all the glyceride molecules present (*random interesterification*). In the case of a two-component blend, such as a liquid oil and a solid fat, interesterification gives a more complex spectrum of glycerides than would be obtained by simple physical mixing. The result is a plastic fat that melts gradually over a wide temperature range rather than a semisolid oil with high-melting components. Interesterification can also be used to eliminate some triglyceride components that tend to dominate the crystallization behavior of a mixture (e.g., to remove troublesome triglyceride species from lard or palm oil, see Section 2.2.7).

Interesterification is catalyzed by heavy-metal salts such as tin(II) chloride or by fatty-acid soaps of the alkali metals. These are generally introduced at a level of about 2 %. For such catalysts to be effective, the reaction must be carried out at about 200 °C. More efficient catalysis is provided by such compounds as the sodium salts of the short-chain alcohols (sodium methoxide or ethoxide), sodium glyceroxide, or anhydrous sodium hydroxide, all at a level of about 0.5 % or less. Reaction then proceeds at a much lower temperature (≤ 60 °C), reaching completion within a few minutes. This is a much more efficient technique for random interesterification. Moreover, it permits *directed interesterification*, in which the reaction is conducted at such a low temperature that the high-melting glycerides tend to crystallize during the reaction. The highest melting fatty acids are thus effectively removed, and equilibrium is displaced toward the formation and removal of even more of the high-melting glycerides. This continues until no more high-melting acids remain in the reaction mix. The result is segregation of the higher melting acids into a stearin fraction, which can be removed by fractionation. Application of this technique to sunflower oil gives an oil with a lower content of saturated fatty acids and a corresponding increase in polyunsaturated acids.

The use of sodium compounds as catalysts requires that the oil be dry, neutral, and protected by an inert atmosphere, since water, fatty acids, and oxygen all deactivate the catalyst. A common procedure calls for carrying out the reaction under vacuum so that water is removed rapidly. A sodium-based catalyst cannot be recovered from the reaction mixture because it is ultimately converted to soap. Any active catalyst remaining after interesterification is deactivated by the addition of a dilute acid (e.g., acetic acid). Sodium salts and soaps are then removed by washing, which is followed by a light earth bleaching and final deodorization.

3.1.2.4. Fractionation

Fractionation entails separating a fat into fractions with different melting ranges by crystallization and subsequent removal of the crystals (→ Fats and Fatty Oils, Chap. 7.). Such a process might be carried out for various reasons: to remove very high melting components (e.g., the stearin from beef tallow), to concentrate PUFA acids (as in removal of stearin from a directively interesterified sunflower oil), or to select a frac-

tion with a relatively sharp melting range for use as a hardstock component. The latter objective requires two-stage fractionation involving removal of both a stearin and an olein fraction to leave a mid-fraction. The process has been applied to palm oil to obtain a fraction rich in monooleodipalmitin and also to interesterified blends of lauric-rich fats with fats rich in stearic and palmitic residues, thereby producing a fraction rich in monolaurodipalmitin or -distearin glycerides.

Fractionation can be carried out either in a solvent or "dry". Acetone, light hydrocarbons, and methanol are used for *solvent fractionation.* The fat is first dissolved by heating it in the solvent, after which the solution is cooled to a temperature at which crystallization takes place. The temperature required depends on the oil being treated. In a typical palm-oil fractionation, for instance, an acetone solution of the oil is cooled to ca. 20 °C to precipitate the stearin, then to 0 °C to precipitate the mid-fraction. The resulting fat crystals are removed by filtration and solvent is recovered by distillation. Solvent fractionation gives a clean separation of the various glycerides, but it is an expensive operation because of the specialized equipment required for the handling and recovery of highly flammable solvents. Normally it is applied only to fats for products carrying a premium relative to ordinary margarine (e.g., confectionery fats).

In *dry fractionation,* liquid components of the oil blend (i.e., the olein) act in effect as solvents for the solid components or stearin. This means that "solvent" occluded in the separated stearin cannot be removed by distillation as in solvent fractionation. Instead, it remains as part of the stearin composition and the resulting separations are less clear-cut than in solvent fractionation. In order to achieve maximum separation efficiency special care must be taken in the choice of crystallization conditions. The rates of cooling and stirring are particularly critical for producing crystals with the best form for easy separation.

Separation techniques other than filtration may also be used to maximize separation of the olein. One such technique is pressing, in which slabs of stearin are squeezed between the plates of a hydraulic press. This is particularly effective for removing a small amount of olein from a large amount of stearin, as in the preparation of palm kernel stearin. Another valuable technique is the Lanza separation. Here the crystal slurry is stirred with an aqueous detergent solution, typically sodium lauryl sulfate. The detergent solution preferentially wets the solid fat crystals and draws them into the aqueous phase. Olein is then separated from the aqueous phase by centrifugation, leaving the stearin in the aqueous phase. The stearin is recovered by heating this mixed phase above the melting range of the stearin, followed by further centrifugation.

3.2. The Aqueous Phase

The aqueous phase comprises ca. 15 % of a conventional margarine but it can account for 60 % or more in a low-fat spread.

3.2.1. The Aqueous Phase in Conventional Margarines

In conventional margarine the aqueous phase consists mainly of water, and its main function is as a carrier of flavoring components. In some parts of the world, special flavors are common (cf. Section 2.1), but in the Western World margarine is expected to taste as much like butter as possible. Considerable research has been devoted to achieving this end. Most of the effort has focussed on identifying the natural flavor components in butter. This resulted initially in the introduction of diacetyl and short-chain fatty acids. Later work led to the use of the γ- and δ-lactones of C_8–C_{14} hydroxy fatty acids. Most manufacturers now employ their own closely guarded "flavor cocktails". Butter-like flavor is enhanced by use in the aqueous phase of skimmed milk that has been ripened with lactic acid bacteria.

Another flavor-contributing component of the aqueous phase is salt. The salt level must be carefully adjusted to correspond to the preferences of a particular national market.

3.2.2. The Aqueous Phase in Low-Fat Spreads

In low-fat spreads the aqueous phase not only carries the flavor components but also contributes to the structure of the product. Thus,

with a fat content ≤ 40 % it is necessary to invoke special techniques to ensure adequate rigidity. Rigidity can be achieved in two ways. A spread in which the aqueous phase is essentially water, can be stiffened by the use of powerful emulsifiers which disperse the water more finely and stabilize the resultant droplets. Such stable, highly dispersed droplets augment the limited number of fat crystals present in the system (cf. Chap. 4), thereby increasing the effective size of the elastic crystal network. The extent to which this principle can be applied is limited, however; an emulsion that is too stable adversely affects the mouthfeel of the product, producing an initial thick, heavy sensation that is followed by a rapid watery breakdown. The alternative is to thicken the aqueous phase by adding components that either gel the water or increase its viscosity to such an extent that the dispersed water droplets behave like semisolid particles. Components that have been used for this purpose include gelatin, caseinates derived from milk proteins, water-soluble carbohydrate gums (e.g., carrageen and locust bean gum), and modified starches. Additives are introduced at levels of 5 – 15 % depending on type. Together with the processing conditions such additives can significantly affect the mouthfeel of spreads, and the creamy breakdown associated with conventional margarines is more easily achieved in low-fat spreads in which thickeners have been used than in one with an unthickened aqueous phase.

3.3. Emulsifiers

Emulsifiers are essential to both conventional margarines and low-fat spreads. They facilitate dispersion of the aqueous phase and also stabilize the resulting dispersion. A typical emulsifier contains both polar and nonpolar groups. Since the affinities of these groups for the two phases differ, the emulsifier tends to concentrate at the phase interface. This alters both the interfacial tension and the interfacial viscosity, thus aiding the formation and stabilization of droplets of one phase dispersed within the other. Whether the dispersion is one of water in oil or oil in water depends on the relative number and nature of polar and nonpolar groups, the so-called hydrophilic – lypophilic balance (HLB). Emulsions are discussed in detail elsewhere (→ Emulsions).

The emulsifiers most widely employed in margarine and other spreads are monoglycerides and lecithins. In *monoglycerides*, polar character is provided by two free hydroxyl groups, and nonpolar character by the long-chain fatty acid moiety. Monoglycerides are prepared by interesterification of natural triglyceride oils with glycerol and concentrated by distillation.

In *lecithin,* nonpolar character is again conferred by long-chain fatty acid residues, but the polar component is the phosphatidyl moiety attached to the third hydroxyl group of glycerol (→ Lecithin). The lecithin most widely used in margarine occurs as a natural component of soybean oil and is separated from the oil at the degumming stage of refining.

Margarines designed for special applications (e.g., pastry) may incorporate specially selected emulsifiers to enhance particular end-use properties (see Section 5.1).

3.4. Minor Components

Minor components added to margarines include antioxidants, coloring agents, preservatives, pH regulators, and vitamins (→ Foods, 3. Food Additives).

The preferred *antioxidants* are tocopherols, which may be either synthetic or derived from natural sources, but synthetic compounds such as butylated hydroxytoluene (BHT) or butylated hydroxyanisole (BHA) are sometimes used instead. The antioxidants pick up or release free radicals in the course of assuming stable quinone or hydroquinone configurations and thereby interrupt the chain of free radical reactions responsible for autoxidation (→ Antioxidants). Natural tocopherol antioxidants occur in most vegetable oils, so that the use of antioxidants is generally limited to fat blends consisting primarily of animal fats.

Coloring agents are usually carotenoids. Examples include β-carotene, either from palm oil or synthetic, and annatto, a mixture of bixins derived from the Central American fruit of that name.

a) Perforated steam coils; b) Heating jacket outlet; c) Salt solution inlet; d) Milk inlet; e) Oil inlet; f) Vents; g) Hinged flap; h) Inspection glass; i) Stirrer with pierced plates; j) Heating jacket outlet; k) Product outlet

The most widely used *preservative* for the control of biological activity is common salt, but in some circumstances potassium sorbate is added, particularly in low-fat spreads where increased water content favors microbial growth. Control of the pH may also be used to inhibit biological activity. Control of pH is also necessary in spreads in which the aqueous phase has been thickened with proteins (e.g., caseinates) because the resulting viscosity or elasticity is a function of pH. Salts of weak acids (e.g., sodium citrate or sodium phosphate) are used for this purpose.

Most food control authorities require the addition of vitamins A (27 – 33 IU/g) and D (2.8 – 3.5 IU/g) to margarine as a means of assuring adequate nutritional value.

4. Processing

Margarine processing procedures are designed to achieve three objectives:

1) dispersion of the aqueous phase as a water-in-oil emulsion throughout the fat phase,
2) formation of a fat crystal network to stabilize the resulting emulsion and give the product some degree of firmness, and
3) modification of the crystal network to produce the desired firmness and confer plasticity.

Figure 2. Cooling drum systems for margarine production (reproduced with permission from [1])
A) Double-drum system; B) Single-drum system with feeding rollera) Cooling drum; b) Scraper; c) Collecting wagon; d) Trough; e) Feed roller

Common procedures can be broadly classified according to whether these objectives are achieved independently (churn process) or simultaneously (votator process).

4.1. Churn Process

The churn process was the only one applied to margarine production prior to the mid-1930s.

In the first stage, *emulsion formation,* the aqueous phase and the fat phase, together with minor ingredients, are introduced into a stirred jacketed vessel at a temperature just above the melting range. The stirrer consists of a pierced plate that occupies the whole cross-section of the vessel (Fig. 1). The two phases are then mixed vigorously to produce a fine water-in-oil emulsion.

In the second stage, *crystal formation,* the emulsion is rapidly chilled by passage through heat exchangers or by use of a drum cooler (Fig. 2). In the drum cooler a thin layer of emulsion is spread on the surface of a cooled rotating drum and scraped off with a blade. As a result of rapid cooling, crystal nuclei develop and grow to form the network required for product rigidity. This initial product is too brittle for commercial use, however, and it must therefore be subjected to *plasticization*, in which it undergoes mechanical working (plodding) to break down part of the crystal network. Appropriate mechanical processes include extrusion through a screw press, squeezing through a gap between rollers, or agitation by rotating knife blades.

4.2. Votator Process

The term "Votator" was first coined by the Girdler Company in the United States to describe the continuous cooler – stirrer unit that they introduced in 1936. A flow scheme for the votator process is shown in Figure 3. Two votator units are involved in margarine production, the A unit and the C unit.

The *A unit* consists of a jacketed tube fitted with a rotating shaft that fills most of the cross section of the tube, leaving an annulus of 5 – 10 mm. This annulus is occupied by blades attached to the rotating shaft and touching the inner wall of the tube. The jacket is cooled by a refrigerant such as liquid ammonia. The shaft is rotated at high speed ($\geq$ 500 rpm) and the product mixture is forced through the annulus. It is thus subjected to rapid cooling by contact with the refrigerated walls of the jacket as well as to high shear.

The *C unit* also consists of a jacketed tube with a rotating shaft, but the shaft is smaller in diameter relative to the cross section of the tube, so the annulus is much wider. Moreover, the shaft is fitted not with wall-scraping blades but with a series of pegs. As the shaft rotates, the pegs move between similar pegs attached to the inner wall of the tube, subjecting the contents of the C unit to mixing at controlled temperature but not to the high shear conditions prevailing in the A unit.

Figure 3. Schematic diagram of a votator plant with precrystallization and recycling (Unilever)
a) High-pressure metering pump; b) C unit; c) Pump; d) A unit; e) B unit

The required proportions of fat and aqueous phases may be continuously stirred in a premix tank to create a loose emulsion suitable for pumping into the votator line. Alternatively, the components may be pumped from independent holding vessels into the votator line through a proportionating pump adjusted to produce the required volume ratio.

The combination of high shear and rapid cooling in the A unit results in a finely dispersed emulsion with an even distribution of fine fat crystals. Low shear agitation in the C unit permits further growth of these crystals without the formation of an interacting crystal network. Only under subsequent quiescent conditions is further crystal growth able to produce such a network. Thus, it is the C unit that controls the ultimate plasticity of the product. If all the crystal nuclei emerging from the A unit were allowed to grow into crystals, all contributing to the crystal network, then the product would be too brittle.

A typical votator installation utilizes combinations of A units and C units coupled in series. The manufacturer selects a set of temperatures, residence times, and agitation conditions specifi-

cally tailored to the mixture composition and the required product type.

A further unit, the *B unit*, is necessary for margarine that is to be packaged in a paper wrapper. This unit consists of an open tube corresponding in cross-section to the final wrapped slab. The tube is without a rotating shaft, so product passes through with minimum agitation. This not only molds the product into the required shape for packing but also provides the degree of product firmness necessary for handling in a wrapping machine.

Product that is to be packaged in tubs or cartons is extruded directly into the container from the last votator unit. Firming proceeds to completion in the container during subsequent storage. The success of this technique depends on precise control of the degree of crystal network formation in the processing line, i.e., on an optimal balance of A- and C-unit working. "Overworking" (premature formation of a crystal network, which is subsequently destroyed by further mechanical working) produces a product that is too liquid, because most of the crystallization takes place in the absence of an interactive network. Such a product only becomes firm in the tub after prolonged storage, if at all. At the other extreme, too much potential for crystal growth in product leaving the line leads to excessive posthardening and a birttle product. Nevertheless, some posthardening must occur in the tub, since attempting to extrude stiffened product would result in high back pressure along the line, which would in turn interfere with the mechanical working of the system.

The votator system is intended for continuous operation, but it is nonetheless subject to occasional stoppages, with breakdown of the packaging equipment being the most common cause. Interruption of throughput typically results in product setting up in the votator line, with the potential for considerable loss of product, time, and energy. Consequently, the whole system (the mixture composition and the lay-out of the processing units) is designed to facilitate recycling without altering the nature of the final product or the settings of the processing parameters.

A satisfactory production line must also include provision for regular and rigorous cleaning and sanitization to eliminate the possibility of microbial contamination. This entails pipelines for detergent solutions as well as steam lines for equipment scalding. It is especially important to avoid dead pockets that might trap partially processed material and serve as isolated breeding grounds for microorganisms.

5. Specialty Margarines and Shortenings

Most margarines are intended for spreading on bread, but some are also used in cooked foods, including cakes and pastries, as well as in the preparation of fried foods. Specialty margarines exist for commercial use in the latter applications.

5.1. Pastry Margarines

Pastry margarines are mainly used for short crust pastry, cake mixes, and flaky pastry; i.e., flour confections in which fat is a major ingredient. Such baked goods differ considerably from bread. In *bread making*, the object is to work the dough so that it develops a gluten structure; i.e., protein molecules within the flour grains are encouraged to link up to form long chains and extended sheets, providing the characteristic cellular structure of bread. Fat is kept to a minimum in bread mixes because fat levels > 3 % interfere with the development of gluten structure. In *short crust pastry* the aim is reversed. Long protein chains are not allowed to develop, resulting in a product that is crumbly and, unlike bread, breaks easily into small fragments when bitten. This is achieved by giving the pastry mixture a relatively high fat content– ca. 30 % or more. Individual grains of flour thereby become coated and the gluten structure cannot extend from grain to grain. Baked pastry consists essentially of an aggregate of partially gelatinized starch granules cemented together with fat. The fat must therefore be easily and intimately mixed into the flour, and it must also have sufficient solid content to contribute to the rigid structure of the finished pastry. This calls for a fat blend containing relatively high-melting components together with a reasonable proportion of liquid fat, thereby providing plasticity over a wide temperature range. Animal fats such as lard and beef suet have traditionally been used for this purpose, but more

precise control of favorable properties is possible through the use of blended oils, including palm oil and hydrogenated vegetable oils. Water is essential only as a flavor carrier. Indeed, too much water renders the pastry sticky due to overgelatinization of the starch. The final water content of a mix must usually be adjusted by the baker to suit a particular flour, so margarine especially designed for short crust pastry frequently contains less water than conventional margarines.

The products referred to as *shortenings* contain no water. Soft, pumpable shortenings have been developed to meet the needs of large-scale bakers and confectioners, who must handle ingredients in bulk. Such shortenings are collected from the votator line in bulk containers. They are delivered in tankers and stored in bulk storage tanks. Storage and transport containers are held at 20 – 25 °C to maintain a pumpable consistency.

Cake mixes resemble short crust pastry mixtures in that they yield a product with a rigid, yet easily fragmented texture. However, a cake mix must rise (i.e., expand) during baking to produce a foam of air bubbles entrapped in baked dough. This effect depends upon the creaming power of the dough, i.e., its ability to entrap air during the mixing process. Here the water phase is an asset: not only does water dissolve air during the mixing stage but it is also converted to steam during the baking stage, thus increasing the number and volume of entrapped bubbles. Emulsifiers also enhance the creaming effect, so that cake margarines and shortenings often have a high monoglyceride content (2 – 5 % compared to 0.5 % in conventional margarines). This is the basis for the term *high ratio shortenings* [17]. Such a blend permits incorporation at a higher level of water into the mix as well as a higher ratio of sugar to flour, resulting not only in a greater volume increase but also a tenderer crumb and one that is less liable to go stale on keeping.

The creaming effect is inhibited by fat blends that contain a preponderance of a single glyceride species. Natural lard, for instance, is not ideal for cake making because of its high oleodipalmitin content, but its performance is greatly improved if this glyceride is broken down by interesterification [18].

The characteristic texture of *flaky pastry* in which thin layers of pastry are separated by layers of air, results from a special cake structure in which air is present not in the form of spherical bubbles but as laminae separating continuous layers of pastry. To achieve this the margarine or shortening is not intimately mixed into the flour as in a normal cake mix but remains in discrete, evenly distributed layers. In one process the fat is added to the dough mix in small lumps. The mixture is then rolled out, flattening the lumps of fat into layers. In an alternative process the dough is rolled out first and the margarine or shortening is subsequently spread over its surface. A further layer of dough is then rolled on top, followed by another layer of fat, and so on. During baking, air and water in the margarine layers expand, forcing the dough layers apart and producing a flaky texture. Margarine designed for this application must be plastic enough to be spread or rolled into thin layers, but not so soft as to diffuse into the surrounding dough layers before starch gelatinization has set these into flakes. Thus, a fat blend is required that offers a wide range of plasticity but a limited proportion of liquid oil [19].

5.2. Frying

Butter has traditionally been a popular medium for frying, so it is not surprising that attempts have been made to use margarine for the same purpose. However, the performance of the two substances in this application is not the same. Whereas butter can be heated without difficulty to the high temperatures required for frying (140 – 200 °C), margarine tends to spatter. Not only does this cause anything in the vicinity of the frying pan to become covered with fat droplets, but spattering is also a potential fire hazard, since the aerosol of fine fat droplets is highly flammable.

Spattering occurs because the fat crystals that help to stabilize the emulsion disappear as the margarine is heated above its melting range. The aqueous-phase droplets thus coalesce into relatively large drops. During frying, water is heated well above its boiling point. Since the water drops are suspended in liquid oil, there is little chance for the nucleation that would initiate evaporation. Instead the drops become superheated. When nucleation eventually does occur (e.g., by contact with the walls of the frying

pan), the drops vaporize very rapidly. The result is a minor explosion as a small volume of liquid water is converted to a significantly larger volume of steam over a very short period of time. Spattering is a consequence of numerous drops undergoing this violent transition over a short period of time.

In butter the water droplets are stabilized by encapsulation in casein micelles. Coalescence is thus inhibited and the droplets can diffuse to the surface, where they evaporate as foam. This desirable state can be approached in margarine by the use of suitable emulsifiers (e.g., the citrate esters of mono- and diglycerides, fatty acid esters of polyglycerol, and lecithin) [20].

Low-fat spreads are unsuitable for frying not only because of their high water content, but also because the gums or proteins used as thickeners are denatured at frying temperature and form unpleasant charred residues on the bottom of the pan.

Shortenings and frying oils do not contain an aqueous phase, so spattering problems do not arise. Spattering occurs here only when water is introduced along with the food that is to be fried (e.g., as lumps of ice on frozen food). In these cases the physical and chemical properties of the fat blend are thus the only factors to be considered in the choice of a frying medium.

As noted in Section 2.2.7, liquid oils are unsaturated, and therefore more susceptible to oxidation than saturated solid fats. Choice of a suitable blend for frying is therefore reduced to achieving a balance between the handling convenience of a liquid oil and the oxidative stability of a solid fat.

The domestic user tends to favor liquid oil, especially for deep frying. It is easier to heat a pan of liquid oil on a domestic stove than to melt a block of solid fat. Furthermore, the domestic user is not overly concerned with oxidative stability, since a given batch of oil is only used for a limited number of fryings. The favorable nutritional properties of liquid oils also have a strong influence on domestic users.

For the industrial fryer, on the other hand, oxidative stability is of major importance because the useful lifetime of an oil is an important economic factor. Industrial frying is a continuous process and is thus dependent upon keeping the oxidative state of the oil at an acceptable level. Ideally, an equilibrium is attained between removal of used oil from the fryer by incorporation into the fried product and addition of fresh oil; the level of oxidation products in the oil in the fryer thus remains constant. The rate of oxidation must be equal to the rate of turnover of the oil, a requirement that can to some extent be met by proper design of the fryer and adjusting the rate of throughput of product. Nevertheless, the oxidative stability of the oil is also a major factor.

Thus, for the industrial fryer, the preferred frying medium is a solid or semisolid fat. Solid fats present a minor inconvenience in that they are liable to congeal in pipelines and holding tanks, but this problem is readily overcome by the installation of suitable heating equipment.

Economic considerations are also important for small-scale commercial fryers, such as restaurants, canteens, and fast-food shops. However, a chef is in more direct contact with the frying process than is the quality control manager of a large frying operation, permitting a quicker reaction to changes in product quality. The choice of fat is therefore influenced heavily by personal preference and local tradition.

6. Packaging

Packing units for margarine vary in size from the very small individual packs used in restaurants (containing only a few grams of product), through domestic packs (250, 500 g), larger packs (25, 50 kg) for commercial bakers and caterers, up to tanker loads of several tonnes for industrial users.

Wrapping materials for retail packs should provide a barrier to both light and air to inhibit autoxidative deterioration, and they must be impermeable to fat and water to prevent leakage and consequent spoilage. For hard-blend margarines, greaseproof parchment paper adequately serves the latter purpose, but aluminum foil is also widely used because of its impermeability to both light and air. Soft blend margarines and low-fat spreads require rigid containers such as tubs made from plastic or waxed cardboard. In all cases the packaging material must be devoid of potentially harmful components that might migrate into the contents. Thus, plastic containers or wrappers must not contain residual monomers, fillers, or other harmful ma-

terials. Appropriate specifications and tests have been drawn up by food regulation authorities (→ Foods, 4. Food Packaging, Chap. 8.).

7. Economic Aspects

Tables 3 and 4 show the changes in pattern of consumption of butter, margarine and low fat spreads over recent years in the geographical areas for which figures are available.

The decrease in total fat consumption is evident in all regions. This reduction is mainly at the expense of butter relative to the other spreads. This is dramatically apparent in the United Kingdom figures. However, the United Kingdom was traditionally an area of high butter consumption. The effect is not apparent in the Netherlands figures where butter consumption has been low compared to margarine for some years. The increase in consumption of low-fat spreads compared to conventional margarine is, however, apparent in both those countries.

1. Introduction

Matches are readily available in every country of the world. The match industry grew rapidly during the 1800s, but it is now declining in most developed markets due to reduced smoking, competition from mechanical lighters, and the growth in automatic ignition on domestic appliances. However, match usage is still growing in some developing countries such as India.

Worldwide production is estimated at around 6×10^{12} matches per year. To put this into context, if they were all placed end to end they would measure about 260×10^6 km, enough to reach to the sun and most of the way back. During every second of every day about 190 000 matches are being struck.

The match industry uses about 6×10^6 trees each year for making match sticks (splints), and a similar number of trees are felled to make cardboard for the outer boxes. To make the head composition, some 120 000 t of chemicals are used worldwide. The match industry is the most significant user of potassium chlorate, it is the only consumer of phosphorus sesquisulfide, and it has a significant demand for red phosphorus.

2. History

The development of matches depended on the availability of the right materials and an understanding of chemistry. In the early 1800s both of these factors had advanced sufficiently to make the invention of matches possible. Of particular significance was the manufacture of phosphorus and potassium chlorate on an industrial scale. From ca. 1820 to 1840, there was a rush of inventions relating to different types of matches.

The history of matches is documented in [4 – 6]. Here only a few key highlights of the history that caused significant changes to matches or the structure of the industry are mentioned.

The first matches, or friction lights as they were then known, appeared in 1826 and they were produced and sold by JOHN WALKER, a pharmacist from Stockton on Tees in the United Kingdom. These matches consisted of wooden splints tipped with a mixture of antimony sulfide and potassium chlorate together with a binder. They could be ignited by striking the tip on a rough surface. These matches were sold in bundles.

The Walker matches were not very sensitive and the phosphorus match, invented by SAURIA in the 1830s soon superseded them. These matches contained white (or yellow) phosphorus and were much easier to light. Like the Walker matches they were ignited by striking against a rough surface. These matches were so sensitive that sometimes they would ignite spontaneously if left in the sun. Furthermore, white phosphorus is very toxic, and this would have a significant effect on the development of the match industry.

Up until this point in the development of matches, all ingredients necessary for easy igni-

10.1002/14356007.a16_163.pub2

tion were contained in the match head. Typically the active components were a powerful reducing agent (e.g., white phosphorus) together with a powerful oxidant (e.g., potassium chlorate). In 1844 Pasch invented a new type of match in which the powerful reducing agent (he used red phosphorus, the nontoxic and less reactive form of phosphorus) was painted on the side of the box, and the match head contained the powerful oxidant (potassium chlorate). These matches could only be struck on the painted friction surface on the side of the box. The Pasch match was developed and produced by the Lundstom brothers in Jonkoping, Sweden. The matches were known as safety matches because they were nontoxic, in contrast with the Sauria phosphorus matches containing white phosphorus.

At this stage in the development of matches the methods of production were simple and labor-intensive. The splints were cut by hand and manually placed in perforated plates or frames for dipping, boxes were made manually by outworkers, and the matches were packed by hand. From 1862 onwards the process was revolutionized by the work of Alexander Lagerman who single handedly developed machines for mass producing splints and for dipping and packing the product. The techniques developed by Lagerman for carrying out these processes are broadly similar to the techniques that are still in use today.

For a long time the Sauria phosphorus matches and the Pasch safety matches were produced and sold generally. However, the toxicity of white phosphorus led to a severe occupational disease, one of the first to be identified, amongst match workers called phosphorus necrosis (phossy jaw). Phosphorus matches were also responsible, accidentally or intentionally, for some deaths amongst the general public. To protect the public and the match workers, the sale of phosphorus matches was prohibited in Finland in 1872. Over the next 20 years more and more countries outlawed the sale of phosphorus matches, and in these countries the Pasch safety match then dominated the market.

In 1898 Sevene and Cahill invented a new type of match, in which toxic white phosphorus was replaced by the much less toxic phosphorus sesquisulfide. These matches could be struck on any rough surface, like the Sauria phosphorus matches. The use of white phosphorus in matches declined rapidly after this as all manufacturers changed over to the new compound.

The consequence of this history is that those countries that banned the use of white phosphorus between the years 1870 and 1900 even today only consume safety matches whereas those that banned the use of white phosphorus after 1900 use both safety matches and phosphorus sesquisulphide matches (usually called strike-anywhere matches).

The use of white phosphorus in matches was eventually banned throughout the world by international treaty (The Berne Convention, 1902). This is one of the few treaties banning the use of a substance on a global scale.

Until 1990 all matches contained some toxic heavy metals and sulfur. Increasing environmental pressures have caused a few manufacturers in Western Europe to develop new formulations that do not contain these substances.

Throughout the development of matches wood has been the preferred stem material by most manufacturers. However, in some countries other materials are used for the match stem. In Spain, Italy, and some Latin American countries, stems are made from waxed paper that is crimped and shaped into rods by pulling it through a forming die. For advertising matches, cardboard is often used for the stem. The cardboard is punched and cut into strips with teeth, and each tooth is tipped with match head composition. These combs are then fastened inside a cardboard cover that carries the advertising message.

Aside from the traditional matchbox (for retail matches) and matchbooks (for advertising matches) various other types of containers or packaging have been developed and used but they have never seriously rivaled the traditional forms of packaging.

No account of the history of matches can omit mention of the Swede, Ivar Kreugar. After the end of World War I, Kreugar acquired match manufacturing operations around the world until he eventually controlled 60 % of the world production of matches. This lead to the establishment of the Swedish Match company (Svensk Tandstickor AB) that dominated world trade in matches. Kreugar committed suicide in 1932, and today the Swedish Match company is still a global company with interests in matches, match manufacturing machinery, lighters, and tobacco

products, albeit with a much smaller share of the world match trade.

3. The Matchmaking Process

Match making is typically carried out in integrated plants where wood, cardboard and chemicals are the raw materials and the fully packed matches are the output (see Fig. 1). However, not all match factories make there own splints. Many factories buy in ready-made splints. These are usually supplied in boxes, although in some cases they are strapped together in big bundles known as cheeses.

3.1. Splint Manufacture

Wood Handling and Pretreatment. Wood arrives at the factory in the form of logs, typically 3 m long and 200 – 400 mm in diameter. These are stacked in log piles until they are needed in the process. During dry weather these piles are sprayed with water to prevent the wood from drying out.

The logs are brought into the factory when needed. If the logs are frozen then they are first thawed in steam-heated chambers. Some species, notably the resinous pines, also require steam cooking to soften the timber before further processing.

Crosscutting and Debarking. After pretreatment the logs are cut into billets about 600 mm long. The bark is removed from the billets. Sometimes the logs are debarked before cross-cutting into billets.

Peeling, Chopping, and Sieving. The debarked billets pass to a peeling lathe where they are rotated against a sharp knife, and the log is converted into a continuous sheet of veneer. To produce veneer with the best strength, the timber must be saturated with water at this stage. If it is too dry then the veneer will be weak and full of cracks.

The veneer is cut into sheets about 3 m long and stacked into a pile that is fed continuously to a chopper that guillotines through the pile of veneers. As the guillotine knife passes through the stack it is preceded by some knives at right angles to the guillotine blade and pitched the length of the desired match splint apart. Thus at each stroke of the guillotine blade the veneer is cut into individual match splints. Splints as cut contain about 50 % water.

The splints leaving the chopper contain some short splints and some long splinters. These arise from the edges of the billet and from where knots are cut. It is usual to remove as much of this waste as possible at this stage by butt sieving.

Impregnation. The splints are impregnated with a chemical to prevent after glow. Usually this is ammonium dihydrogen phosphate or diammonium hydrogen phosphate. Impregnation can be carried out by dipping the splints into a bath containing a dilute solution (ca. 2 %) of the afterglow inhibitor or by spraying the splints with a more concentrated solution (ca. 12 %) of the afterglow inhibitor in a rotating drum. The latter procedure is preferred since less water is added to the splints and consequently less water has to be evaporated during the drying process.

Drying. The impregnated splints are then dried. Usually the splints fall onto a flat perforated conveyor and pass through a heated drying chamber maintained at 80 – 100 °C. The residence time in the dryer is typically about 30 min. In the dryer a strong airflow is maintained through the bed of splints, and water-saturated air is exhausted. The drying conditions are critical; too high a temperature leads to scorching of the splints, which discolors and weakens them, while too low a temperature or air flow leads to poor drying and problems in the following polishing process. The typical water content of the splints is about 3 % after drying.

Polishing, Cleaning, and Sieving. At this stage the splints are dry but they are rough, i.e., the surface of each splint has many protruding fibers. The splints are passed to a rotating polishing drum where they are tumbled together. In the tumbling process the small protruding surface fibers are rubbed off, and the splints become much smoother. If the splints are dry then the surface fibers are brittle and the splints polish well. If the splints have a water content greater than 4 %, then the surface fibers are much tougher, and polishing is much less effective. Sometimes blocks or flakes of wax are added to the polishing drum. This is said to increase the effectiveness of the polishing process.

Figure 1. Schematic diagram showing match production

The butt sieving carried out immediately after chopping does not completely remove short splints. Furthermore, many intrinsically weak splints are broken during the subsequent impregnation, drying, and polishing operations. Hence, after polishing, the splints must be cleaned and sieved to remove undersized pieces. In the first stage of this process the splints pass down gently sloping vibrating tables with holes in. The diameter of the holes is just under half the splint length. Short splints pass through the holes, whereas those of correct length pass over the screen. Many strongly curved splints are also removed in this sieving operation. After this sizing to the correct length the splints then fall onto a second sieving table. On this vibrating table the splints fall into a series of small cups or pockets which maintain them vertical. The bottom of each pocket is perforated with holes that permit only splints with the required cross section to pass. All the oversize splints remain in the pockets. The finished sieved splints then pass to bunkers for storage.

Waste. At each stage in the process some wastage occurs. Bark is rejected, as are the first cuts into the billet on the peeling machine. On the peeling machine it is not possible to peel right through to the center of the log. Usually a center core of about 75 mm in diameter is rejected at the end of the peeling operation. More waste material is filtered out during the butt sieving and final sieving and cleaning operations. Typically only 40 – 50 % of the logs entering the process is recovered as good splints. The remaining 50 – 60 % is waste. This is typically converted to chips and used as fuel for a boiler to generate process steam, which supplies heat for the drying operation and other processes in the factory.

3.2. Outer-Box Making

Printing. Various processes are used to print the outer box. These can be reel fed (for large

printing runs) or sheet fed (for smaller printing runs).

One variant uses a dedicated printing machine (Chambon machine) to take reels of cardboard up to 500 mm wide and produce cut printed skillets complete with friction paint. The printing process can be letterset or, more commonly these days, offset litho, enabling high-quality, high-definition, full-color images to be reproduced. UV inks (ultraviolet curing inks) and varnishes are commonly used, and these facilitate high-speed printing (web speeds of up to 140 m/min can be achieved). Friction paint is applied at the same time by using a gravure printing process. The friction paint is water-based, and high-speed radio-frequency drying is performed immediately after friction-paint application. After printing, the web passes through a rotary cutter, creaser, and stacker mechanism. The stacked bundles of skillets are supplied to the box-forming machine.

In another process, sheets of cardboard are fed to a conventional printing machine and printed. The printed sheets then pass to a second machine where the friction surface is applied by a gravure printing process. The sheets then pass to a third machine where they are then diecut and creased to form the skillets in a press. The skillets are then stacked into bundles.

In a third variant sheets are printed and cut into strips. Each strip consists of many skillets with the friction surfaces aligned together. The strips pass over a creasing roll and then a coating roll that applies a continuous strip of friction paint along the length of the strip. The strips are dried with hot air or IR lamps. The dried strips are slit into separate skillets and stacked in bundles.

There are other variants for producing printed skillets with a friction surface, but the three outlined above are the most common. Many match factories purchase ready made printed and creased skillets complete with the friction surface from specialist suppliers.

Folding. To produce the outer boxes, bundles of skillets are loaded onto a bar machine. In this machine skillets are fed from the bottom of the bundle by a conveyor system under a bar with the internal dimensions of the box outer. A fast setting glue (usually animal glue) is applied to one edge of the skillet, and the skillet is folded around the bar to form the outer box. A typical bar machine can produce outer boxes at speeds of around 1100 boxes per minute. It is common practice, nowadays, to feed the boxes directly to the match assembly line so that the orientation of the outer box with respect to the inner is always maintained.

Other types of machines for making outer boxes are available, but these are usually much slower than a bar machine. Consequently several machines are necessary to supply boxes at a sufficient rate to feed the match-assembly machine. This leads to complex conveyor systems on the infeed of the match line.

3.3. Inner-Box Making

Inner boxes are produced from reels of cardboard. The board is fed to the inner-box machine, which stamps out the correct shape, applies adhesive, and folds the box into its final form. Modern inner-box machines do the forming and gluing on a rotating drum and work at similar speeds to the outer box bar machine. Older machines punch and press each box individually, and these work at slower speeds. Several of these are then necessary to supply one match assembly line.

3.4. Composition Making

The making of match head composition used to be carried out in relatively small batches of around 50 kg. Each batch would be passed through a cone mill to ensure good dispersion of all the ingredients. This practice is very labor intensive and results in considerable batch-to-batch variation.

Match head compositions typically contain water, animal glue (as binder), potassium chlorate (as oxidizer), inert materials, sulfur or red phosphorus, and various minor ingredients to control foaming, viscosity, and microorganism growth. In addition to these ingredients, it is also important that the match composition contains a controlled amount of finely dispersed air.

Modern practice is to prepare composition in much larger quantities (ca. 500 kg) in a high-speed dispersing mixer to ensure uniform dispersion of all the ingredients. Normally, hot water is added to the mixer at the start, and then animal

glue, and the mixture is stirred at low speed until the glue is dissolved. The rest of the ingredients are then added, and the stirrer speed is increased. Once the ingredients are well dispersed, air is injected into the bottom of the mixer. Air injection is stopped once the composition reaches a certain volume. In this way it is possible to produce large quantities of head composition with a consistent amount of entrained air.

3.5. Match Assembly Line

The match assembly line, also known as the continuous machine, is fed with splints, paraffin wax, head composition, inner boxes, and outer boxes. The line assembles these components to form the finished boxes of matches.

Splints are fed from a hopper into a system that aligns them and punches them in rows into perforated steel bars about 1.5 m wide. At each stroke of the machine, one row of splints is inserted into a row of holes. The bars are linked together to form a continuous mat that conveys the splints through the whole process.

The splints are preheated by passing them over a heated plate (ca. 100 °C). This ensures satisfactory absorption of paraffin wax in the next stage.

The tips of the warm splints pass continuously through a bath of paraffin wax, typically maintained at 125 – 155 °C. The tips are immersed into the wax to a depth of ca. 5 mm and for from 2 – 5 s. The paraffin wax is the main fuel that sustains the flame once the match is alight.

After dipping in paraffin, the splints again pass over a heated plate that allows the paraffin wax to remain liquid so that it can be absorbed by the wooden splint. If paraffin wax remains on the surface of the splint, adhesion of the match head is compromised.

After this post-heating the splints are allowed to cool for ca. 3 min before they reach the composition-dipping station.

All the previous stages take place with the bar mat moving continuously. At the composition dipping station the bar mat must stop moving. A number of bars are pressed down so that the tips of the matches are dipped in the head composition. The splits are withdrawn slowly from the head composition to form a well-shaped match head.

The surface of the head composition must be continuously scraped (except during dipping) to prevent the formation of a skin. Various mechanisms have been designed to do this but the band-dip mechanism is generally recognized as being the best.

After dipping, the bar mat again moves continuously. A "lost-motion" mechanism is incorporated around the dipping station to facilitate this transition from continuous movement to intermittent movement and back to continuous movement.

After dipping, the matches remain on the continuous machine conveyor for ca. 40 – 60 min to allow the match heads to dry. To facilitate this, the conveyor zigzags vertically or horizontally along the length of the machine.

The conveyor finally brings the matches to the punch out. Here the matches are pushed out of the bars with pins and they fall into cups that then transfer them to the boxes. The inner and outer boxes are supplied on separate conveyors to the punch out mechanism.

After filling, the boxes are closed, usually in two stages. First the inner box is pushed about half way over the outer box. The surface of the outer box is then brushed to push any protruding matches into the box. Then the box is completely closed.

The boxes finally pass to an automatic wrapping station where they are wrapped in packets of 6, 10, or 12. Polypropylene film is generally used for wrapping, but paper wraps are also used. There are many packing options for the wrapped packets. The most common is to pack them into stout cardboard cases containing about 1000 boxes, although trays, caddies, and other packs are also common. Packing can be done by hand or automatic machines, depending on labor costs and the sophistication of the plant.

The continuous machine typically has 2×10^6 matches on the conveyor at any one time, and the production rate is around 2.4×10^6 matches per hour (up to 75 000 boxes per hour depending on the contents of the box).

Production of strike-anywhere matches is in general similar to the production of safety matches. The most important difference is that the outer box skillets are not printed with friction

paint. The skillets are formed into outer boxes. The rough friction surface is applied to the box either before or after filling the boxes.

4. Raw Materials

The main raw materials for making matches are wood, cardboard, paraffin wax and chemicals.

Wood. Wood for making match splints must satisfy several criteria:

- It must be straight grained and easy to peel on a peeling lathe.
- It must be stress-free while it dries; otherwise, the splints become too curved during the drying process.
- It must be strong. The higher the strength of the timber the thinner the cross section of the splints can be and the greater the yield of splints per cubic meter of timber.
- It must be tough and fibrous. Some timbers are strong but very brittle. If matches made from such timber broke during striking, then the end with the burning head is liable to detach from the part that is being held, leading to a potentially hazardous situation. Under the same conditions, splints made from tough fibrous timber break but the two halves remain attached to one another.
- The timber must be porous so that it will absorb paraffin wax. Wax is the main fuel for the burning of the match once the head has finished burning. It is important for the wood to absorb sufficient paraffin wax and that little remains on the surface of the wood after dipping.
- From the viewpoint of appearance the color of the wood should be as light as possible.

The preferred timber for match splints is Baltic aspen (*Populus tremaloides*). This is widely distributed in Northern Europe, and the principal producers are Sweden, Finland, the Baltic States, and Russia. Aspen is rarely, if ever, planted as a commercial timber crop. Aspen occurs adventitiously amongst other timber stands. It propagates readily by suckering, especially after felling. It grows fast and tends to establish itself rapidly and in so doing gains a head start on other species in the competition for light. Similar species exist in North America, and Canadian Aspen has also been extensively used for making match splints.

In Southern and central Europe, various poplar species are used for matchmaking. These timbers are softer, weaker, and more absorbent than aspen. Poplar is also used in the Americas and in Asia.

In other parts of the world many species are used for matchmaking, but in general these lack strength, and frequently are darker than Aspen. Notable are the various pine species (such as *Pinus ellioti*), araucaria, white mutti (India), and morototo.

Ideally timber should be converted into splints immediately after felling. In this state it is saturated with water and is hence easy to peel. However this ideal situation rarely applies and it is necessary to store the timber before use. It is important that stored logs are kept wet during dry weather and that they are properly thawed out before processing if they are frozen.

Wood is a natural product whose properties vary considerably from tree to tree, with the season, with the climate and with the soil. In addition, storage conditions affect the properties and processing of timber. There is thus always a spectrum of properties and a considerable variation from one splint to another.

Cardboard. Cardboard for box making must also satisfy certain criteria:

- It must be stiff enough to form a rigid box that will adequately protect the matches.
- It must print well. This is especially important in the fully developed European and North American markets.
- It must cut cleanly and crease easily.
- The friction paint must adhere well to the board. Certain coatings that are applied to the board may interfere with the good adhesion of the friction paint to the box.
- The board must glue well. Generally the water absorption of the reverse side of the board must be high to promote good adhesion and fast setting of the box-making adhesive.
- The board must not soften too much on exposure to high humidity.

Cardboard for box making varies considerably. Generally it has a basis weight of around 275 – 350 g/m^2 and a thickness between 0.5 and 1 mm. In developed markets, light coated board that provides good printability is used for the

outer boxes. Recycled boards are commonly used for both inner and outer boxes.

Paraffin waxes. Paraffin waxes for matchmaking are mainly derived from petroleum. Satisfactory waxes usually have melting points in the range 49 – 55 °C. The other important parameter is the oil content of the wax. If this is too high then head adhesion may be adversely affected, and if really excessive then the heads may be desensitized and the box stained because the oil migrates into the head and the cardboard. Generally waxes with oil contents up to 7 % are satisfactory, although new waxes should always be checked before implementation into production to ensure that the appearance and performance of the product is unaffected. Synthetic (Fischer – Tropsch) waxes have also been used, as has stearin.

Chemicals. *Ammonium dihydrogen phosphate* (monoammonium phosphate, MAP) is used for splint impregnation as an afterglow inhibitor. It is an acid salt and the materials of construction of the impregnation unit and dryers must be compatible with the substance. The specification of the material is not critical, but it should be free from gross contamination. Insoluble matter can cause problems with spray impregnation systems.

Diammonium hydrogen phosphate (diammonium phosphate, DAP) is an alternative to ammonium dihydrogen phosphate. It is an alkaline salt and it causes much less corrosion of mild steel than ammonium dihydrogen phosphate. However, a greater concentration of the diammonium salt is needed to achieve the same degree of afterglow inhibition. During the drying process, considerable amounts of ammonia are released, and this can make the working environment unpleasant.

Potassium chlorate is the major ingredient of most match head formulations, and it accounts for up to 60 % of the dry head weight. It is the principle oxidizing agent in matches. The most important properties of potassium chlorate for matchmaking are the particle size and the sodium content. The particle size has a great influence on the burn rate of the head, and it must be closely controlled. The sodium content is important, since a high sodium content makes the match heads hygroscopic, and this can severely limit the sensitivity and performance in high-humidity environments. Potassium chlorate tends to form lumps on standing, and often a small amount (ca. 0.5 %) of anticaking agent (such as tricalcium phosphate) is added to the salt before it is packed.

Animal glue (technical gelatin) is the most widely used binder for match head composition. It is extracted by partial hydrolysis of animal hides or bones. During the hydrolysis the collagen present in the hides or bones is broken down and becomes soluble in hot water. In addition to its binding properties glue has important influences on other properties of match head composition:

- It controls the viscosity of the head composition.
- It is the main fuel present in the match heads.
- It is an air-entraining agent and foam stabilizer. It thus has an influence on the amount and stability of the air entrained in the composition.
- The animal glue is only partly burned during the burning of the head composition and the carbon remaining is a component of the ash left by the head. This carbon has an influence on the propensity of the ash to drop off.
- It is a good dispersing agent and it helps to keep all the head composition components well dispersed.

Solutions of animal glue gel on cooling. The gel point is around 28 °C for good-quality glue. The quality of glue is measured by the Bloom jelly strength test and by the viscosity. Generally glues with a Bloom value of around 300 g or more are most suitable for matchmaking. High-Bloom glues usually have a high gelling temperature and permit matchmaking at high ambient temperatures. The ash content should be low (< 2 %).

Animal glue is also frequently used as an *adhesive* for outer boxes formed on the bar machine. For this purpose, glues of very high Bloom strength (ca. 400 or more) are required.

Casein is sometimes used instead of animal glue in tropical countries. It provides better resistance to humidity, but the heads are more brittle.

Many head compositions contain a *starch*, a *starch derivative*, or a *cellulose derivative* (e.g., hydroxyethyl cellulose or ethyl hydroxyethyl cellulose). These contribute to the binding of the

head, but their main function is to modify the viscosity and dispersing properties of the mix.

Sulfur is a common component of match heads. Usually powdered sulfur is used.

Red phosphorus is added to some head compositions as well as being the main ingredient in the friction paint. For head composition and for printed friction paint the maximum particle size should be ca. 50 µm. No large particles should be present. For friction paint to be applied by roller, a coarser grade of red phosphorus can be used. Phosphorus tend to become acidic in storage. This tendency can be greatly reduced if the phosphorus particles are coated with a stabilizer, usually magnesium oxide. These stabilized grades are normally used for matchmaking.

Phosphorus sesquisulfide is the active ingredient in strike-anywhere matches. It is produced by the reaction of white phosphorus with sulfur. It smells strongly of hydrogen sulfide due to slow hydrolysis in normal damp air.

Potassium dichromate is frequently added to head composition as a sensitizer. It is usually dissolved in the water used for making the mix.

Manganese dioxide is usually finely ground natural pyrolusite. It is sometimes added to head composition and to friction paint. It may act as a sensitizer and/or pigment.

Various *inert materials* are added to match head composition to moderate the reaction. These are mainly siliceous materials like silica, feldspar, powdered glass, diatomaceous earth, and kaolin. Basic materials like magnesium carbonate, calcium carbonate or zinc oxide are usually added to prevent the composition from becoming acidic. In general, these materials play little part in the chemical reactions that take place, but they do have a profound influence on the stability of the ash and the speed of burning.

Colorants include various dyes such as eosine or rhodamine, or pigments such as red iron oxide (Fe_2O_3), black iron oxide (Fe_3O_4), or manganese dioxide. The prime function of these is to impart color, but some dyes do seem to affect the glue properties, and the pigments may affect the sensitivity and/or ash stability.

Various *antifoams* may be added to control foam during composition making. Usually these are polyoxyethylene derivatives. After the head composition has been prepared, a *foam stabilizer* may be added. Usually these are alkyl aryl sulfonate salts.

5. Head Composition

Match compositions are always made up as an aqueous slurry with a water content of about 40 % by weight of the dry solids in the mix.

For best sensitivity, burning characteristics, and ash stability the head composition, safety or strike-anywhere, must contain about 25 vol % of entrained air dispersed as very small bubbles in the mix. This corresponds to a mixture density of about 1.25 g/cm^3.

Safety Matches. A typical head composition for safety matches contains the following ingredients:

Potassium chlorate	50 – 60
Glue	9 – 12 %
Starch or cellulose derivative	0 – 3 %
Inert materials	25 – 35 %
Sulfur	0 – 5 %
Red phosphorus	0 – 1 %
Potassium dichromate	0 – 1 %
Colorants	0 – 3 %
Foam stabilizer	0.1 %

For the common brown safety match heads, iron oxide is usually added to the mix as a colorant. For colored matches, the inert materials are carefully selected to have a light color, and a dye is added. Good white matches are difficult to make. For best results only white inert materials are used, no potassium dichromate is added, and the composition is heavily loaded with titanium dioxide pigment.

Strike-Anywhere Matches. A typical strike-anywhere head composition contains the following ingredients:

Potassium chlorate	35 – 45 %
Glue	10 – 20 %
Phosphorus sesquisulfide	5 – 10 %
Inert materials	35 – 45 %
Colorants	0 – 1 %
Antifoam	trace
Foam stabilizer	0.1 %

6. Friction Surfaces

For safety matches the friction paint is an important functional part of the match box. In principle, strike-anywhere matches can be struck on any rough surface. In practice they are generally struck on the rough surface provided on the box.

Safety Matches. Friction paint for printed friction:

Red phosphorus	60 – 80 %
Poly(vinyl/acetate)	20 – 40 % (as dry solids)
Antifoam	1 – 2 %

The water content of a typical paint for a Chambon printing machine is ca. 60 % by weight of the dry solid. No fillers are added, as these rapidly wear the doctor blade that scrapes the gravure cylinder.

Friction paint for roller applicator:

Red phosphorus	50 – 70 %
Poly(vinyl/acetate)	10 – 20 % (as dry solids)
Inert fillers	10 – 40 %

The water content of friction paint for roller application varies widely and must be adjusted to suit the applicator conditions.

Strike-Anywhere Matches. Friction surfaces for strike anywhere matches can be produced in many ways:

- A strip of abrasive paper can be stuck to the side of the box as the box is formed.
- The boxes on the bar machine are coated along one edge with an aqueous binder (usually urea – formaldehyde resin) as they are formed and then sprayed with sand that adheres to the wet binder. The boxes leave the bar and the frictioned surface is heated to cure the resin before the box is fed to the continuous machine.
- The boxes on the bar machine are coated along one edge with hot-melt adhesive as they are formed on the bar machine. The coated boxes are allowed to cool to solidify the hot melt adhesive strip and then fed to the continuous machine. After filling, the boxes are sprayed with hot sand that then adheres to the hot-melt adhesive. The advantages of this latter method are that the sand is applied after the continuous machine, so that the abrasive wear on the machine parts is reduced and the line can be made more compact.
- The boxes can be coated with a wet, gritty slurry by means of a roller applicator. Such slurries generally contain poly(vinyl acetate) binders, siliceous grit, and a thickening agent. UV-curing resins have also been used as binders.

7. The Chemistry of Matches

The chemistry of matches is not well understood, even though the product is 150 years old. The reactions taking place can be conveniently divided into three parts: the initiation phase, the head-burning phase and the splint-burning phase.

The Initiation Phase. The initiation phase begins when the match head is placed in contact with the friction. This puts the potassium chlorate in the head into close proximity with the red phosphorus in the friction surface. Any movement of the head causes the potassium chlorate and phosphorus to mix together. At the same time the interface between the head and the friction is heated by the work done in rubbing them together. The reaction of red phosphorus with potassium chlorate has a very low activation energy, and it can be postulated that this is the first reaction to take place:

$$5\,KClO_3 + 6\,P \rightarrow 5\,KCl + 3\,P_2O_5$$

This reaction is strongly exothermic and quickly causes further heating of the interfacial area until it is hot enough to start the second phase of the reaction.

The amount of air entrained in the mix has a considerable influence on the force required to strike matches. For normal head composition, this is about 25 vol %. In the past it was argued that this air somehow takes part in the initiation phase. However, this seems improbable, since 1 cm^3 of head composition contains 0.25 cm^3 of air, 0.05 cm^3 of which is oxygen. This is equivalent to 0.07 mg of oxygen, which compares with the 200 mg of oxygen contained in the potassium chlorate present in the same volume of head composition. It seems unlikely that such a small amount of oxygen can have a serious influence on the initiation phase. Furthermore it has been demonstrated that carbon dioxide bubbles are just as effective as air bubbles in sensitizing matches. A more likely explanation of the sensitizing action of the entrained air is that it reduces the thermal conductivity of the head composition. Hence, less of the frictional heat leaks into the head, and a higher temperature is achieved at the interface with the friction surface for the same mechanical work input. Conversely, the same interfacial temperature can be achieved with less input of mechanical work, i.e., the matches are more sensitive.

Another illustration of the importance of thermal conductivity of the system is provided by the fact that it is possible to strike safety matches, albeit with great difficulty, on a smooth surface like polished glass. It is in fact even easier to strike matches on a smooth polished silica surface that has a lower conductivity than glass, but it is impossible to strike matches on smooth polished stainless steel surface, which has a much higher conductivity than glass.

The Head-Burning Stage. The active ingredients in the head are potassium chlorate, animal glue and either sulfur or red phosphorus. These latter two ingredients are present in much smaller amounts than the animal glue. Furthermore, it is known that match heads without sulfur or phosphorus can be readily struck, so it can be argued that sulfur and phosphorus are not essential to the main reaction. Thus the principle reaction taking place is that between potassium chlorate and animal glue.

This strongly exothermic reaction can be expressed as follows:

$$\mathrm{C}_v\mathrm{H}_w\mathrm{O}_x\mathrm{N}_y\mathrm{S}_z + (2/3v+1/6w-x/3+2/3z)\,\mathrm{KClO_3} \rightarrow$$

$$(2/3v+1/6w-x/3+2/3z)\,\mathrm{KCl}$$

$$+v\mathrm{CO_2}+w/2\mathrm{H_2O}+y/2\mathrm{N_2}+z\,\mathrm{SO_2}$$

Even without sulfur or phosphorus it is easy to initiate the above reaction, but some times it spreads as a dull red glow throughout the material without the appearance of a flame. It can be argued that the reaction temperature is insufficient to ignite the gases formed by pyrolysis of the material ahead of the glowing zone. The inclusion of sulfur or phosphorus in the composition gives rise to some phosphorus or sulfur vapor in the pyrolysis products, and that these lower the spontaneous ignition temperature of the pyrolysis gases in the surrounding atmospheric oxygen, causing instantaneous ignition with the appearance of flame.

The underlying wood impregnated with wax also plays some role in the head reaction, since the pyrolysis products from the wood and wax also mix with the pyrolysis products formed ahead of the reaction zone.

The inert materials, mainly silicates, present in the mix serve to moderate the reaction of the active chemicals. These slow down the reaction by absorbing heat. The residue left after combustion of the head must also fuse and flux together to leave a stable ash that does not fall from the splint. The silicates present provide this fluxing action in combination with the molten potassium chloride that remains from the decomposition of the potassium chlorate. It is the correct choice of the inert materials that renders a match safe to use (i.e., smooth burning, nonexplosive, and not spitting or dropping hot ash).

The other important ingredient in the match head is a fine dispersion of small bubbles. The effect of these on sensitivity was noted above. However, the presence of these dispersed voids also controls the rate of burning of the head. Generally the greater the volume fraction of bubbles, the faster the head burns. The porosity also has an influence on the stability of the ash residue.

The reactions taking place are complex and involve interactions between the solid phases present at the start of the reaction, between the volatile pyrolysis products and the surrounding air, as well as various reactions involving the intermediate products. Often quite small changes to the formulation, such as the removal of potassium dichromate from the composition, can have a profound effect on the sensitivity and burning properties of the match head, as well as completely changing the structure and stability of the residual ash left behind.

The Splint-Burning Phase. By the time the head finishes burning the underlying paraffin-wax-impregnated wood has been heated quite strongly and is producing copious amounts of paraffin vapor, which is already alight and burning in the surrounding air. This in turn heats the splint ahead of the flame front, generating more vapor, and thus the flame transfers from the head to the splint and then travels along the splint consuming the paraffin as it progresses.

The main reaction taking place is the combustion of the paraffin vapor:

$$\mathrm{C}_n\mathrm{H}_{2n+2} + (3/2n+1/2)\,\mathrm{O_2} \rightarrow n\,\mathrm{CO_2} + (n+1)\,\mathrm{H_2O}$$

The wood takes relatively little part in this reaction. Indeed, on splints without paraffin wax the flame always extinguishes once the head has finished burning.

Wood consists mainly of the carbohydrate cellulose together with some lignin. Dry wood is readily combustible since the pyrolysis products are inflammable. Typically dry, unimpregnated wood yields combustible pyrolysis prod-

ucts on heating to 400 °C. The residue is charcoal that continues to glow in air with short blue flames. However, the splints for matches are impregnated with ammonium phosphate to prevent afterglow. This modifies the pyrolysis reaction considerably. On heating, the ammonium phosphate is pyrolysed to phosphoric acid. The phosphoric acid catalyzes the dehydration of the carbohydrate to carbon and steam [7]:

$$(C_6H_{10}O_5)_n \rightarrow 6n\,C + 5n\,H_2O$$

The consequence is that few combustible pyrolysis products are formed on wood treated with ammonium phosphate. The steam evolved merely serves as a diluent for the paraffin vapor. This dilution of the wax vapor with steam results in larger flame heights. The char left on pyrolysis of wood treated with ammonium phosphate is much more inert than the char from unimpregnated wood and consequently it does not readily react with the oxygen in the surrounding air. Thus, any tendency for the wood to continue glowing (afterglow) once the flame is extinguished is suppressed.

Strike-Anywhere Matches. The chemistry of strike-anywhere matches is basically similar to that of safety matches. The only difference is that the active reducing agent, phosphorus sesquisulfide, and the potassium chlorate are both in the match head. During striking, these two ingredients are ground together and heated by friction. The reaction has a low activation energy and gives phosphorus and sulfur oxides:

$$16\,KClO_3 + 3\,P_4S_3 \rightarrow 16\,KCl + 6\,P_2O_5 + 9\,SO_2$$

The relation between the oxygen supply present in the oxidizer and the oxygen demand of the reducing agents present in the match head can vary widely. Most safety matches contain a slight excess of oxygen, whereas most strike-anywhere matches are highly oxygen deficient. However, there are many examples of perfectly acceptable oxygen-deficient safety matches that have been produced.

Other Match-Head Systems. Relatively few combinations of active chemicals produce satisfactory friction matches. The combinations of potassium chlorate with red phosphorus, antimony sulfide or phosphorus sesquisulfide are the only systems that are currently used for making matches. A few other systems have been investigated, such as those based on potassium chlorate and calcium hypophosphite or lead thiosulfate, and shown to have some friction-sensitive properties. However, these are not as good as the more traditional systems, and they are not cost effective. Attempts to replace the potassium chlorate with other oxidants such as potassium nitrate or potassium perchlorate result in matches that are difficult or impossible to strike.

Matches have been made, in the past, from combinations of white phosphorus with other oxidants such as potassium nitrate, lead dioxide or even calcium carbonate that also function well. However, these would be unacceptable today because of the toxicity of white phosphorus.

8. Match Testing

Match tests are time-consuming and subjective. Typical tests that are carried out on matches follow:

- Count: the content of the box is counted.
- Appearance: the quality of the print, the friction surface, the splints, and the match heads are judged visually, often by comparison with reference samples. Match heads must have the correct shape and be without cracks or other damage, since these could lead to detachment of pieces of head material during striking.
- Splint strength can be assessed by using a pendulum gauge to measure the energy absorbed in breaking the splint or by applying a static load to the center of a splint supported at the two ends.
- Head adhesion can be measured by applying a load to the head to try to pull it off.
- Head impact strength is assessed by measuring the load, applied with a small drop hammer, that cracks the head.
- Strike test: matches are struck manually in a defined way using the minimum force to achieve ignition. Evidence of explosion or fragmentation, of dropping ash, of breaking splints, of afterglow; ignition of the friction surface; flame height; and flame duration are recorded.
- Durability of the friction surface: the usual requirement is that all the matches can be struck on half the available friction surface.

– Sensitivity. The minimum force required to ignite the match can be assessed with a strain-gauge force sensor and a peak measuring meter.

9. Match Standards

There are many national standards for matches. The only international standard is the CEN Standard EN 1783 (Matches — Performance Requirements, Safety and Classification), published by CEN in 1997.

10. Quality Assurance

Matches pose some unique challenges to a quality-control manager:

– Matches are produced at very high production speeds (ca. 2.4×10^6/h).
– Match testing is slow and laborious. In the time it takes to make a complete test to confirm conformance to the performance tests of EN 1783, a continuous machine will have produced about 10×10^6 matches.
– The costs of testing are very much higher than the cost of production. In the time it takes for one person to test the strike performance of 125 matches, another can produce 330 000 matches.
– The important tests are destructive, so high rates of testing would be uneconomic even if they were feasible.
– Production is not serial, which would allow automatic tests on every match, but parallel, with many matches produced at each stroke of the machine.
– Consumer expectation of defects is very low (complaints are measured in parts per billion), but sampling methods for testing can only detect defects at the level of 0.1 %.
– Matches are made from natural materials and derived products (wood and cardboard) that do not always behave in a predictable way.
– Some match defects lead to potentially hazardous, even life-threatening, situations. For example, detached burning heads or accidental ignition of matches can cause fires.

In practice it is impossible to measure the product quality to provide total quality assurance, since sampling methods can only detect defects at the 0.1 % level, whereas acceptable consumer quality requires some defects, such as head fragmentation during striking, to be at very much lower levels. The only way is to control the process. If the process has been stable and the resultant product quality has been acceptable in the market then there is no reason why, if the process is controlled to have the same process conditions, that it should not continue to produce satisfactory product. This means setting tight limits on all controllable variables and raw materials and constantly checking them to ensure that the process is within the control range. All changes to the process or raw materials must be closely monitored to ensure that there are no adverse effects on quality or consumer satisfaction. Product testing is used to supplement process controls to ensure that matches meet the performance and safety requirements of internal or external standards.

11. Safety and Handling

Match manufacturing is potentially a hazardous process since it involves handling highly reactive materials such as potassium chlorate and red phosphorus. Good practice demands that the highly reactive oxidants and reductants are kept in separate storage areas and that they only come together when they are processed to make the match-head composition. This mixing is always carried out in the presence of water and each component is well wetted and dispersed before adding the next. Once the head composition is prepared it is relatively safe to handle provided it is never allowed to dry out (except on the splints of course) and that good housekeeping is practiced.

On the continuous machine the head composition is applied to the splints and allowed to dry. The greatest potential for fire occurs when the matches are punched out into the match boxes. The matches at this stage are almost dry. A fire at the punch out will spread rapidly to all the matches on the continuous machine. Such incidents do occasionally happen in production (usually if the machine has stopped for some time and the matches have become very dry before boxing). However, continuous machines

are robustly built to withstand such fires and the operators are trained in fire-fighting techniques. Fires on match machines can be extinguished with carbon dioxide or water. Automatically triggered fire extinguishers are frequently fitted at the machine punch out.

Once the matches are boxed and packed into cases they represent little danger. Even if a case falls from a considerable height, and some boxes ignite inside the case, the fire usually self extinguishes because there is insufficient oxygen in the packaging to sustain burning. However, cases of matches should be stored in a cool, dry place and separated from highly flammable materials. The ignition temperature of matches is greater than 125 °C so there is no danger of self-ignition in normal storage environments.

In normal use there are relatively few serious accidents involving matches. It should be noted that many accidents involving matches result from children playing with fire and due care should be taken to ensure that matches are stored out of their reach

Melamines (2,4,6-triamino-1,3,5-triazines) are produced from urea. They are used in the fabrication of melamine – formaldehyde resins for laminating and adhesive applications. Melanine is used as cross-linker in heat-cured and high-solids paint systems.Guanamines (2,4-diamino-1,3,5-triazines) are produced from dicyandiamide and the corresponding nitrile by base-catalyzed cyclocondensation. They are used in similar polymer applications as for melamine. They give a lower cross-link density and higher flexibility because only two amino functionalities are present.

1. Introduction

Melamine was first prepared and described in 1834 by Liebig, who obtained it from fusion of potassium thiocyanate with ammonium chloride. In 1885, A. W. von Hoffmann published its molecular structure. Melamine [*108-78-1*] (2,4,6-triamino-1,3,5-triazine), $C_3N_6H_6$, M_r 126.13, exists mainly in the amino form:

Not until 100 years later did melamine find industrial application in the production of melamine – formaldehyde resins (→ Amino Resins). The first commercial plants came on stream in the late 1930s. Since that time melamine has become an increasingly important chemical commodity. In 1970, world capacity was estimated at 200 000 t. Production in 1994 is 610 000 t/a. Most of the melamine produced is still used in the fabrication of melamine – formaldehyde resins.

Until about 1960, melamine was prepared exclusively from dicyandiamide [*461-58-5*] (→ Cyanamides, Chap. 3). This conversion was car-

10.1002/14356007.a16_171.pub2

ried out in autoclaves at 10 MPa and 400 °C in the presence of ammonia, according to the equation

$$3\ H_2NC\,(NH)\,NHCN \rightarrow 2\ C_3N_6H_6$$

In the early 1940s, MACKAY discovered that melamine could also be synthesized from urea [*57-13-6*] at 400 °C with or without catalyst [6]. Today, melamine is produced industrially almost exclusively from urea. Most processes using dicyandiamide as raw material were discontinued or replaced at the end of the 1960s.

2. Physical Properties

Melamine is manufactured and sold as fine, white, powdered crystals. The most important physical data for melamine are summarized in the following list [7, 8]:

mp	350 °C (subl.)
Density ϱ	1.573 g/cm^3
Dissociation constants	
K_{b1} (25 °C)	1.1×10^{-9}
K_{b2} (25 °C)	1.0×10^{-14}
Heat of formation ΔH_f^0 (25 °C)	− 71.72 kJ/mol
Heat of combustion (25 °C)	− 1967 kJ/mol
Heat of sublimation (25 °C)	− 121 kJ/mol
Molar heat capacity (25 °C)	155 J K^{-1} mol^{-1}
Specific heat capacity c_p, J kg^{-1} K^{-1}	
at 273 – 353 K	1470
at 300 – 450 K	1630
at 300 – 550 K	1720
Entropy (25 °C)	149 J K^{-1} mol^{-1}
Entropy of formation ΔS_f^0 (25 °C)	−835 J K^{-1} mol^{-1}
Free energy of formation ΔG_f^0 (25 °C)	177 kJ/mol
Solubility (30 °C), g/100 mL, in	
Ethanol	0.06
Acetone	0.03
Dimethylformamide	0.01
Ethyl cellosolve	1.12
Water	0.5

The temperature dependence of the vapor pressure (in 10^5 Pa) in the range 417 – 615 K is described by the following equation [9]:

$$\log p = 9.7334 - 6484.9/T$$

Melamine solubility in water (in grams per 100 g of H_2O) over the range 20 – 100 °C coincides closely with the relationship [10]:

$$\log L = 5.101 - 1642/T$$

Reasonably reliable values can be obtained by means of this equation down to 0 °C.

Crystal Data. Melamine forms monoclinic crystals, space group $P2_1/a$ with a = 1.0537, b = 0.7477, c = 0.7275 nm, β = 112°9′, and Z = 4 [11].

3. Chemical Properties

The chemical properties of melamine are summarized in detail in [1] and [2]. The *s*-triazine ring is very stable and cleaves only under drastic conditions (e.g., heating above 600 °C or fusion with alkali compounds).

By X-ray diffraction studies, crystalline melamine has been shown to exist only in the symmetrical triamino structure; the same is true for the vapor phase and for both neutral and alkaline solutions. Although reactions are in some cases observed at the ring nitrogen atoms (the products being substituted isomelamines), the most important commercial reactions involve only the $-NH_2$ groups, which behave chemically as amido rather than amino functions.

3.1. Thermal Behavior

When melamine is heated above 300 °C in the absence of ammonia or at low ammonia partial pressure, deammoniation and condensation lead to compounds with higher molecular mass. Degradation starts with the release of ammonia and the formation of melem [*1502-47-2*] (2,5,8-triamino-1,3,4,6,7,9,9b-heptaazaphenalene):

Further heating to ca. 600 °C yields more ammonia and melone [*32518-77-7*] [12]:

1

2

Various sources disagree on hydrogen analysis and other analytical data for melone. The material may represent a mixture of substances such as **1** and **2**.

Melam [(*N*-4,6-diamino-1,3,5-triazin-2-yl)-1,3,5-triazine-2,4,6-triamine], [*3576-88-3*] seems not to be an intermediate in the thermal degradation of melamine although the evidence is not entirely clear [12 – 14]. This substance can be prepared by heating melamine salts below 315 °C, and it arises as a byproduct of melamine synthesis.

Melam ($C_6H_9N_{11}$)

The three deammoniation products—melam, melem and melone—are formed reversibly; addition of ammonia at high pressure and temperature regenerates melamine. Indeed, processes for melamine production invariably rely upon excess ammonia to suppress formation of these byproducts. If melamine is heated to 600 °C or higher it is partially cracked, leading to cyanamide along with other products. Hydrogen cyanide may also appear in the crack products, especially in the absence of oxygen [15].

3.2. Hydrolysis

Melamine is hydrolyzed by mineral acid or inorganic alkali. Hydrolysis proceeds stepwise, with loss of one, two, or all three amino groups:

Ammeline

Ammelide

Cyanuric acid

The product spectrum varies with temperature, pH, and concentration; the end product is cyanuric acid [*108-80-5*]. Even small amounts of the oxotriazines (especially cyanuric acid and ammelide) markedly effect the condensation of melamine with formaldehyde by increasing the rate of condensation [16].

3.3. Salt Formation

Melamine is a weak base, forming well-defined salts with both organic and inorganic acids. The melamine ion is assigned the following structure:

The water solubility of organic and inorganic salts of melamine is no higher than that of free melamine (see Table 1). Melamine cyanurate, melamine picrate, and melamine perchlorate are very insoluble in water, and are useful in the quantitative determination of melamine.

3.4. Reaction with Aldehydes

Melamine reacts with aliphatic and aromatic aldehydes to give a variety of products. Most

important is the resinous material obtained from the reaction of formaldehyde with melamine:

$$Me(NH_2)_3 + 6\,CH_2O \rightarrow Me[N(CH_2OH)_2]_3$$

where Me represents that part of the melamine molecule that is not involved in the reaction.

All hydrogen atoms on the melamine molecule can be replaced by methylol groups, and products ranging from the monomethylol to the hexamethylol derivatives have been observed. The methylolmelamines are sparingly soluble in most solvents and are very unstable due to further condensation or resinification, e.g.,

$$MeNHCH_2OH + H_2N{-}Me \rightarrow MeNHCH_2NHMe + H_2O$$

$$2\,MeNHCH_2OH \rightarrow MeNHCH_2OCH_2NHMe + H_2O$$

Melamine – formaldehyde condensation products are characterized by good heat resistance and superior water-resisting properties. They are used, usually in combination with urea – formaldehyde resins, as glues in the woodworking industry, as impregnating resins for decorative laminates, and as a binder in molding materials containing a filler (e.g., cellulose or sawdust). Methylolmelamines can be etherified by heating with alcohol in the presence of an acid catalyst. Industrially most important are the products formed with methanol, *n*-butanol, and isobutanol. They are used as curing agents for surface coatings and as auxiliaries in the paper and textile industries. For additional information see → Amino Resins [17].

4. Production

Melamine can be synthesized from urea at 390 – 410 °C:

$$6\,H_2N - CO - NH_2 \rightarrow C_3N_3(NH_2)_3 + 6\,NH_3 + 3\,CO_2$$

The overall reaction is endothermic, requiring 649 kJ per mole of melamine starting with molten urea at 135 °C.

The processes themselves may be subdivided into two categories:

1) noncatalytic, high-pressure ($\geq$ 8 MPa) processes, and
2) catalytic, low-pressure processes (ca. 1 MPa).

Each type includes three stages:

synthesis
melamine recovery and purification
off-gas treatment

4.1. Low-Pressure Processes

Typical low-pressure processes utilize a fluidized catalyst bed at pressures from atmospheric to ca. 1 MPa and temperatures of 390 – 410 °C. The fluidizing gas is either pure ammonia or the ammonia – carbon dioxide mixture formed during the course of the reaction. Catalysts include alumina and materials of the silica – alumina type. Melamine leaves the reactor in gaseous form together with the fluidizing gas; it is separated from ammonia and carbon dioxide by quenching the gas stream either with water (followed by crystallization) or with cold reaction gas (desublimation).

In the catalytic processes the first reaction step is decomposition of urea to isocyanic acid

and ammonia, after which the isocyanic acid is transformed into melamine:

$$6\,(NH_2)_2CO \longrightarrow 6\,HN{=}C{=}O + 6\,NH_3 \qquad \Delta H = 984\ \text{kJ/mol}$$

$$6\,HN{=}C{=}O \longrightarrow C_3N_3(NH_2)_3 + 3\,CO_2 \qquad \Delta H = -355\ \text{kJ/mol}$$

$$6\,(NH_2)_2CO \longrightarrow C_3N_3(NH_2)_3 + 6\,NH_3 + 3\,CO_2 \qquad \Delta H = 629\ \text{kJ/mol}$$

The overall reaction mechanism is not yet fully understood, but isocyanic acid from the decomposition of urea is believed to be catalytically disproportionated into carbon dioxide and cyanamide or carbodiimide, which then trimerizes to melamine [18 – 20]:

$$6\,HOCN \longrightarrow 3\,[\underset{\text{Carbodiimide}}{HNCNH} \rightleftharpoons \underset{\text{Cyanamide}}{H_2NCN}] + 3\,CO_2$$

$$3\,HNCNH \longrightarrow C_3N_3(NH_2)_3$$

The melamine yield is ca. 90 – 95 % based on urea. Byproducts include melam, melem, and melone, as well as oxotriazines such as ammeline, ammelide, and cyanuric acid. Ureidotriazine is also observed as a product of reaction between melamine and isocyanic acid.

Some byproducts are formed in the reactor during synthesis; others are not generated until the melamine recovery section, where deammoniation or hydrolysis occurs [20 – 29].

Worldwide, three low-pressure processes are in commercial operation: the BASF process, the Chemie Linz process, and the Stamicarbon process.

4.1.1. BASF Process

The BASF process (see Fig. 1) is a *one-stage,* low-pressure, catalytic vapor-phase process. Molten urea is fed to the fluidized catalytic bed reactor (a) at 395 – 400 °C and atmospheric pressure. Alumina is used as a catalyst, and fluidization is accomplished with an NH_3– CO_2 mixture (the process off-gas).

The reactor temperature is held at ca. 395 °C by molten salt circulated through internal heating coils (b). The fluidizing gas is also preheated to 400 °C. To secure an ammonia-rich atmosphere in the reaction zone, make-up ammonia is added to both the fluidizing gas and the urea nozzles.

Gas leaving the reactor is a mixture of gaseous melamine, traces of melem, and unreacted urea (in the form of its decomposition products isocyanic acid and ammonia), as well as ammonia and carbon dioxide (part newly formed, part fluidizing gas). In addition, the gas mixture contains entrained catalyst fines; coarser catalyst particles are retained by cyclone separators inside the reactor.

The gas mixture leaving the reactor is cooled in the gas cooler (d) to a temperature at which only the byproduct melem crystallizes. Precipitated melem, in the form of a fine powder, is removed together with the entrained catalyst fines in adjacent gas filters (e).

The filtered gas mixture enters the top of the crystallizer (f) where it is blended countercurrently with recycled off-gas (140 °C). The temperature in the crystallizer is thereby reduced to 190 – 200 °C, and more than 98 % of the melamine crystallizes as fine crystals. Melamine is recovered from the gas in a cyclone (g), after which it is cooled and stored. It can be used without further treatment and has a minimum purity of 99.9 %.

The nearly melamine-free gas stream from the cyclone is fed to the urea washing tower (i) where it is scrubbed with molten urea (135 °C), which provides both cooling and washing. Clean gas leaving the urea scrubber (after passing through droplet separators) is partially recycled to the reactor as fluidizing gas and partially recycled to the crystallizer as quenching gas. The surplus is fed to an off-gas treatment unit.

A single-stage reactor has the advantage of converting the corrosive intermediate isocyanic acid immediately to melamine; also, the heat of this exothermic reaction is used directly for the endothermic decomposition of urea, the first step in melamine synthesis.

4.1.2. Chemie Linz Process

The Chemie Linz process (see Fig. 2) is a *two-stage* process. In the first step, molten urea is decomposed in a fluidized sand-bed reactor (b) to ammonia and isocyanic acid at ca. 350 °C and 0.35 MPa. Ammonia is used as the fluidizing gas. Heat required for the decomposition is supplied to the reactor by hot molten salt circulated through internal heating coils. The gas stream

Figure 1. BASF process

is then fed to the fixed-bed catalytic reactor (c) where isocyanic acid is converted to melamine at ca. 450 °C and near-atmospheric pressure.

Melamine is recovered from the reaction gas by quenching with water and mother liquor from the centrifuges (h). The quencher (d) is specially designed to work quickly, thereby preventing significant hydrolysis of melamine to ammelide and ammeline. The melamine suspension from the quencher is cooled further to complete the melamine crystallization process. After being centrifuged, the crystals are dried, milled, and stored. A separate recrystallization step is not required.

Exhaust gas from the quencher is fed to an absorber (m) where carbon dioxide is removed as ammonium carbamate by washing with a lean carbamate solution from the off-gas treatment section. The wet ammonia gas is dried with make-up ammonia. Part of it is compressed and recycled to the urea decomposer, and part is exported. Remaining ammonia and carbon dioxide in the liquid effluent are then recovered in the off-gas treatment section.

4.1.3. Stamicarbon Process

Like the BASF process, the DSM Stamicarbon process (see Fig. 3) involves only a *single catalytic stage*. However, it differs from the former in that it is operated at 0.7 MPa, the fluidizing gas is pure ammonia, the catalyst is of the silica – alumina type, and melamine is recovered from the reactor outlet gas by water quench and recrystallization.

Figure 3. Stamicarbon process
a) Urea tank; b) Reactor; c) Preheater; d) Heating coils; e) Internal cyclone; f) Quench cooler; g) Scrubber; h) Hydrocyclone; i) Desorption column; j) Heat exchanger; k) Heat exchanger; l) Mixing vessel; m) Heat exchanger; n) Dissolving vessel; o) Precoat filter; p) Vacuum crystallizer; q) Pump; r) Heat exchanger; s) Mother-liquor vessel; t) Hydrocyclone; u) Centrifuge; v) Pneumatic dryer; w) Hydrocyclone; x) Absorption column; y) Compressor

Urea melt is fed into the lower part of the reactor (b). The silica – alumina catalyst is fluidized by preheated (150 °C) ammonia, which enters the reactor at two points: at the bottom of the reactor to fluidize the catalyst bed, and at the urea nozzles to atomize the urea feed. The reaction is maintained at 400 °C by circulating molten salt through heating coils within the catalyst bed.

The melamine-containing reaction mixture from the reactor is quenched first in a quench cooler (f) and then in a scrubber (g) with recycled mother liquor from the crystallization section. The resulting melamine suspension is concentrated to ca. 35 wt % melamine in a hydrocyclone (h), after which it is fed to a desorption column (i) where part of the ammonia and carbon dioxide dissolved in the suspension is stripped off and returned to the scrubber. The preceding steps are all carried out at reaction pressure; for the following stages, the pressure is reduced.

The suspension leaving the bottom of the desorber is diluted with recycled and preheated mother liquor and water. Activated carbon and filter aids may also be added. The melamine dissolves completely, although separate dissolving vessels (n) are necessary to allow sufficient time for dissolution. The resulting solution is filtered using precoat-type filters (o). Crystallization of melamine is carried out in a vacuum crystallizer (p), and crystals are separated from the mother liquor by hydrocyclone (t) and centrifuge (u). The crystals are dried in a pneumatic dryer and then conveyed to product bins.

Surplus ammonia must be recovered as fluidizing gas from the wet ammonia – carbon dioxide mixture leaving the desorption column and the scrubber. The hot gas mixture is partly condensed by heat-exchange (k) with the mother liquor from melamine dissolution. The condensate and uncondensed gas are then passed at 0.7 MPa to an absorption column (x). Liquid make-up ammonia is fed to the top of this column to condense any carbon dioxide remaining in the ammonia gas. The ammonia is then compressed and recycled as fluidizing and urea-atomization gas for the reactor.

4.2. High-Pressure Processes

High-pressure melamine synthesis systems differ from low-pressure processes by producing melamine in the liquid instead of the vapor phase. They have the advantage of providing high-pressure off-gas more suitable for use in the urea synthesis facility. Liquid phase operation also lends itself to smaller reaction vessels, but the highly corrosive nature of the system dic-

tates use of expensive, corrosion-resistant construction materials such as titanium.

High-pressure reactions occur without catalyst at > 7 MPa and > 370 °C. In general, molten urea is injected at high pressure into a molten melamine – urea mixture in the reactor, where it undergoes conversion to melamine. Sufficient residence time is provided in the reactor to ensure complete reaction, leading to melamine with a purity > 94 %. Heat is supplied to the reactor either by electric heater elements or by a molten salt heat-transfer system. Various types of off-gas separation and melamine purification follow.

High-pressure synthesis of melamine from urea proceeds via the intermediate cyanuric acid, which is subsequently converted to melamine under high pressure in an ammonia environment [30, 31]:

$$\underset{\text{Urea}}{3\,(NH_2)_2CO} \longrightarrow \underset{\text{Cyanic acid}}{3\,HOCN} + \underset{\text{Ammonia}}{3\,NH_3}$$

$$\underset{\text{Cyanic acid}}{3\,HOCN} \longrightarrow \underset{\text{Cyanuric acid}}{(NCOH)_3}$$

$$(NCOH)_3 + 3\,NH_3 \longrightarrow \underset{\text{Melamine}}{C_3N_3(NH_2)_3} + 3\,H_2O$$

$$3\,(NH_2)_2CO + 3\,H_2O \longrightarrow 6\,NH_3 + 3\,CO_2$$

$$6\,(NH_2)_2CO \longrightarrow C_3N_3(NH_2)_3 + 6\,NH_3 + 3\,CO_2$$

The net reaction is the same as in the low-pressure process.

4.2.1. Melamine Chemicals Process

Melamine Chemicals uses a continuous high-pressure *single-stage* process that produces melamine with a purity of ca. 96 – 99.5 %. Molten urea is converted into melamine in a liquid-phase reactor. The off-gases (ammonia and carbon dioxide) are separated in a gas-separating vessel. Liquid melamine is then quenched in a cooling unit, where liquid ammonia is used to solidify the crystals.

Process Description. Incoming urea is preheated by using it to scrub the reactor off-gas stream. This scrubber performs various functions, including (1) driving off any water that may be present in the urea feed, (2) preheating the molten urea, (3) removing melamine from the off-gases, and (4) recovering excess heat energy for subsequent use. The reactor is heated to ca. 370 – 425 °C with a heating-coil system and pressurized to about 11 – 15 MPa. Mixing is provided by heat convection and generation of gaseous reaction products.

Liquid melamine is separated from the off-gas in a gas separator, the product being collected at the bottom. The separator is held at about the same temperature and pressure as the reactor. The gaseous phase (ammonia and carbon dioxide, saturated with melamine vapor) is removed overhead to a urea scrubber. The melamine stream leaving this separator is then injected into the product cooling unit.

The product cooling unit employs liquid ammonia to both cool and solidify melamine. This is accomplished at a controlled temperature and pressure to minimize formation of such impurities as melam and melem. Product is removed from the pressurized cooling unit through a series of pressure-reducing hoppers. Depending on the required degree of purity, it may then be recrystallized [32].

The off-gas stream represents high-pressure (> 10 MPa) ammonia and carbon dioxide, which can be used directly as feed to the urea facility. Alternatively, this gas stream can be treated in a monoethanolamine (MEA) scrubber to recover ammonia and remove carbon dioxide.

4.2.2. Montedison (Ausind) Process

The Montedison process (see Fig. 4) operates at 370 °C and 7 MPa. The required temperature is maintained by a molten-salt heating system consisting of concentric bayonet-type tubes.

Molten urea at 150 °C is fed to the reactor (a) together with preheated ammonia. Average residence time of the mixture in the reactor is about 20 min. As the reaction mixture leaves the reactor, the pressure is lowered to 2.5 MPa, and the mixture is treated at 160 °C in a quencher (b) with an aqueous solution of ammonia and carbon dioxide to precipitate melamine. The water-saturated mixture of ammonia and carbon dioxide leaving the top of the quencher can be recycled to a plant for urea or fertilizer production.

The aqueous melamine slurry remains in the quencher at 160 °C for some time to decompose unconverted urea and such byproducts as biuret and triuret to ammonia and carbon dioxide. It is then fed to a steam stripper (c), where any

Figure 4. Montedison process
a) Reactor; b) Quencher; c) Stripper; d) Absorption column; e) Heat exchanger; f) Filter; g) Vacuum crystallizer; h) Filter; i) Pneumatic dryer; j) Heat exchanger; k) Cyclone; l) Blower

remaining ammonia and carbon dioxide are removed. Off-gas from the stripper is dissolved in water in an absorption column (d) and this solution is recycled to the quencher.

The ammonia- and carbon dioxide-free melamine slurry leaving the bottom of the stripper is diluted with mother liquor to dissolve melamine. Sodium hydroxide is also added, and the solution is then clarified with activated carbon (f). Melamine is crystallized from the clarified solution in a crystallizer (g) operated adiabatically under vacuum. Melamine crystals are separated from the mother liquor in a rotary filter (h), dried in a pneumatic conveyor – dryer (i), and stored.

4.2.3. Nissan Process

The Nissan melamine process (see Fig. 5) operates at 10 MPa and 400 °C. One characteristic feature is urea washing of the reactor off-gas. For this purpose, molten urea is also pressurized to 10 MPa and passed through a high-pressure washing tower (c) where it absorbs any melamine and unreacted urea present in off-gas leaving the reactor. The urea then flows into the reactor (a) by gravity. Ammonia is also fed to the reactor.

In a so-called level tank (b), effluent from the reactor is separated into gaseous and liquid phases. The gaseous phase passes through the previously described urea washing tower to an off-gas treatment facility. The liquid phase consists mainly of molten melamine. This melt is mixed with hot gaseous ammonia and fed to a "cushion" vessel (e) for aging (i.e., to allow by-products to be reconverted to melamine).

After aging, the melamine melt is quenched (f) under pressure with aqueous ammonia, in which it dissolves. The resulting 20 – 30 wt % melamine solution is retained in the quencher at 180 °C until any remaining impurities have decomposed.

Most of the added ammonia is next removed from the solution in an ammonia stripper (g) (operated at 1.5 MPa) and the solution is filtered. Recovered ammonia is recycled. Crystallization takes places in two crystallizers (k) operated in series. Mother liquor and melamine crystals are separated in centrifuges (l), after which the crystals are dried and crushed before storage.

Further treatment of the mother liquor starts with an ammonia stripper (n), in which oxoaminotriazines precipitate. The slurry from this ammonia recovery tower is therefore alkalinized before being fed to a third crystallizer (o) operating at reduced temperature and pressure. Additional melamine crystallizes here, and after separation from the liquid (p) it is returned to the second crystallizer.

Lowering the pH of the mother liquor causes oxoaminotriazines to precipitate; these are removed by decantation (q). The clear mother liquor is used to absorb ammonia leaving the crystallizers and is subsequently recycled to the

Figure 5. Nissan process

quencher together with ammonia released in the ammonia recovery tower.

5. Quality Specifications

Many consumers of melamine are satisfied with a purity of 99.9 %. Some, however, specify additional measurable criteria such as: content of inorganic ash, moisture, and ammeline-related compounds (alkali solubles); particle-size distribution; pH; resin reaction time; and resin color. Average particle sizes ranging from 15 to 100 µm are available for various applications. The rate of dissolution of melamine in formaldehyde solutions depends on particle size, an important parameter that is generally also reported by producers.

6. Chemical Analysis

Melamine is difficult to characterize by traditional chemical methods. Purity specifications are usually based on differences obtained after subtracting determined impurity levels for moisture, ash, and alkali solubles. Instrumental analysis is possible using liquid chromatography [33] and spectroscopic methods, although melamine tends to form complexes with the pH-control buffers used in liquid chromatography, leading to variability in the UV absorption observed at different pHs. Melamine can be precipitated for quantitative determination as the perchlorate or picrate salt (see Section 3.3).

7. Storage and Transportation

Melamine is stable when stored under normal warehouse conditions. Although not particularly hygroscopic, powdered melamine must still be protected from wetting because, like most powders, it will pack and lump over extended storage periods.

In the VDI guideline 2263 melamine is classified as having a burning index of 2, i.e., during a fire it ignites quickly but the flame is rapidly extinguished. Flammability tests performed in accordance with the EEC guideline 84/449 A 10 showed that a glowing platinum wire (>1000 °C) was not able to produce continous burning of melamine.

Shipping considerations are typical of those for other nonhazardous powders. Melamine is available in standard-weight paper bags and semibulk bags. Bulk shipment is by truck and railroad car.

Table 2. Melamine applications, in percent, by region

Application	Europe	United States	Japan
Laminates	47	35	6
Glue, adhesives	25	4	62
Molding compounds	9	9	16
Coatings	8	39	12
Paper, textiles	11	5	3
Other		8	1
Total	100	100	100

8. Uses

Most melamine is reacted with formaldehyde to produce resins for laminating and adhesive applications [16, 17, 34]. One of the major uses of melamine is in the upper sheet of laminated counter- and tabletops.

Another important use of melamine is as the amino cross-linker in heat-cured paint systems. In this case the methylated methylolmelamine is used, with varying molar ratios of melamine, formaldehyde, and alcohol for different paint system applications. High-solids paint systems for automotive applications also constitute a major market for melamine.

Other uses include the preparation of wet-strength resins for paper, water clarifying resins, ion-exchange resins, plastic molding compounds, adhesives, fire retardants in polyurethane foams, and intumescent paints. Important new applications are under development in the field of fire retardants for polymeric materials, especially polyurethane foams. Applications and uses of melamine differ widely among the main consumer countries or regions. Estimates are provided in Table 2.

9. Economic Aspects

About 18 melamine producers exist worldwide. Rated annual production capacity is ca. 550 000 t (data for 1990/1991; see Table 3). In the last decade the average annual growth rate for melamine consumption was ca. 2 %.

10. Toxicology

Acute Toxicity. From the standpoint of acute toxicity, melamine is not classified as a health risk. The oral LD_{50} for rats is > 5000 mg per kilogram of body weight [35]. Melamine applied to the skin and eyes of rabbits is a non-irritant [35]. Skin sensitization could not be provoked by patch tests on humans [36] or guinea pigs [37].

Table 3. Melamine production capacity worldwide

Country	Company	Capacity, t/a

Genetic Toxicity. Investigations into the potential genetic effects of melamine have included the following tests:

In vitro methods

1) Bacterial tests
2) Ames Test [38]
   Escherichia coli plate test [39]
3) Test with eukaryotes
4) Test with eukaryotes

Saccharomyces cerevisiae (gene conversion) [39]
Rat hepatocytes (DNA repair) [40]
Mouse lymphoma test (point mutation) [41]
CHO cells (chromosomal aberrations) [42]

In vivo methods

Drosophila melanogaster (sex-related lethal test) [43]
Mouse micronucleus test (oral administration of 1000 mg per kilogram of body weight) [44]

In none of these studies could melamine-induced mutagenicity or damage to genetic material be demonstrated.

Metabolism. Investigations into the metabolism and toxicokinetics of melamine showed that a single oral dose of 0.38 mg of ^{14}C-labeled melamine administered to a rat was eliminated unchanged in the urine to the extent of 90 % [45]. The plasma half-life was found to be 2.7 h, with highest concentrations in the bladder and kidneys.

Chronic Toxicity and Carcinogenicity. The target organ system for melamine toxicity after prolonged administration to mice and rats is the urinary tract. Both species were administered, in some cases extremely high doses in the diet (750 – 30 000 ppm; ca. 62 – 2490 mg per kilogram of body weight per day) over periods of 14 d, 90 d, and 2 a. All studies led to changes in the kidney (inflammation, calcified concretions in the proximal tubuli) and bladder (inflammation, ulceration, epithelial hyperplasia, bladder stones). Daily dosages up to 15 000 ppm for mice and 5000 ppm for rats administered in the diet over 14 d produced no changes. Female rats tolerated doses of 9000 ppm/d for 13 weeks without symptoms. The incidence of bladder carcinoma increased only for male rats receiving melamine in the diet over a two-year period (dosage: 4500 ppm). Of eight rats displaying tumors, seven also had bladder stones, suggesting that chronic mechanical irritation of the mucous membranes of the bladder may have been responsible for the tumors. Dosages that do not result in bladder stones are not expected to be carcinogenic. Female rats in this study displayed neither bladder stones nor carcinoma [39, 46].

An initiation-promotion study on female mouse skin failed to reveal any tumor-inducing effect [47]. A single dermal application of 1 μmol of melamine followed by a 31-week treatment (twice a week) with 10 nmol of a promoter (12-*O*-tetradecanoylphorbol-13-acetate) resulted in no increased incidence of tumor-bearing animals.

Reproduction Toxicology. A study reported by Thiersch on the reproduction toxicology of melamine was published in 1957. Intraperitoneal administration of a dose of 70 mg/kg to pregnant rats on days 4 and 5, 7 and 8, or 11 and 12 of pregnancy had no influence on the maternal or fetal development, nor was there any teratogenic effect [48].

11. Guanamines

In the course of heating guanidine acetate, Nencki (1874) obtained a new compound to which he assigned the name "guanamine"; later he changed it to acetoguanamine after the discovery of other homologues. Weith recognized in 1876 that this substance was in fact 2,4-diamino-6-methyl-1,3,5-triazine. The term guanamine has since been applied generally to 2,4-diamino-1,3,5-triazines substituted in the 6-position with alkyl, aryl, or alkaryl residues. Such substances are named on the basis of the carboxylic acid that contains one more carbon atom than is present in the substituent on the triazine ring:

R = CH_3: acetoguanamine
R = C_3H_7: butyroguanamine
R = C_9H_{19}: caprinoguanamine
R = C_6H_5: benzoguanamine

Compounds of this type that have major commercial significance are benzoguanamine [*91-76-9*], $C_9H_9N_5$, M_r 187.20, and acetoguanamine [*542-02-9*], $C_4H_7N_5$, M_r 125.14 [49].

The physical properties of aceto-, benzo-, and caprinoguanamine [*5921-65-3*], $C_{12}H_{23}N_5$, M_r 237.35, are summarized in Table 4. Figure 6 illustrates the most important reactions of aceto- and benzoguanamine [50 – 53]. For information regarding other guanamines and their reactions, see [54 – 56].

Table 4. Physical properties of the most important guanamines

	Acetoguanamine	Benzoguanamine	Caprinoguanamine
mp, °C	277	228	105 – 120[a]
Solubility (at 20 °C), g/L, in			
Water	11.2	0.3	insoluble
Acetone	1.04	18.0	25.2
Benzene	0.07	0.3	11.2
Dimethylformamide	0.88	120.0	67.0

Figure 6. Reactions of guanamines

11.1. Production

2,4-Diamino-1,3,5-triazines can be prepared from several aliphatic C-N-compounds [5] including the historic synthesis from biguanides with esters [57, 58]. Aromatic guanamines can be obtained by Pd-catalyzed Suzuki coupling from 1,3,5-triazine precursors [59]. The only method of industrial relevance, however, involves the reaction of dicyandiamide (cyanoguanidine) with nitriles [60]:

Use of dinitriles leads to bisguanamines. Reaction occurs at 105 – 120 °C in the presence of alkaline catalysts (e.g., KOH) in polar solvents, usually alcohols, and high yields are obtained. The rate of reaction depends on the structure of the nitrile, the nature of the solvent, and the concentration of alkali. Aliphatic nitriles generally react more slowly than aromatic nitriles. The reaction can also be performed under microwave irradiation [61] or in ionic liquids [62].

11.2. Uses

Acetoguanamine is used as a condensation component in amino resins. Occasional use is made of the *pure* resins that result from reaction of acetoguanamine with formaldehyde. Such resins display a high degree of water tolerance and can be cured thermally. The rate of the condensation reaction is considerably less dependent on pH than in the case of melamine. Condensation may be carried out in weakly basic or weakly acidic media. Compared to melamine – formaldehyde resins, the curing of acetoguanamine resins occurs more slowly and at a more acidic pH.

Acetoguanamine is normally used to *modify* melamine – formaldehyde resins, conferring improved elasticity, higher gloss, and reduced resin shrinkage. Main application is in the decorative layer of high-pressure laminates (HPL) used for flooring and, e.g., kitchen plates. Acetoguanamine-modified melamine resins provide high gloss, low stain receptivity, and postforming properties. Even low amounts of acetoguanamine (5-10% based on melamine) are sufficient to allow small bending radii without affecting surface hardness or thermal stability [63]. Newer developments aim at reducing the formaldehyde content of melamine – acetoguanamine resins in order to avoid formaldehyde emissions after production [64]. Due to the relatively high cost of acetoguanamine, mixtures with other modifying agents, e.g., dicyandiamide have been applied, especially for short cycle laminates on wood-based materials [65](see also → Wood). Partially alkoxylated acetoguanamine – formaldehyde resins have been proposed for high-temperature fibers with good flexibility [66]. Acetoguanamine cyanurate, either alone or with melamine cyanurate, serves as an effective flame retardant in polyamides [67, 97].

Benzoguanamine is also used primarily in amino resins. Compared to acetoguanamine, benzoguanamine produces significantly more hydrophobic resins that have lower lightfastness due to the aromatic ring.

The most important application of benzoguanamine is in resins for industrial paints. Methylolated benzoguanamine resins that have been etherified with butanols are compatible with hydrocarbon solvents, oils, and various synthetic resins (e.g., alkyd, polyester, epoxy [68] and acrylic resins [69]). Upon curing, these OH functional resins react with the butoxymethyl groups of the benzoguanamine resin to form new cross-links, by splitting off butanol. In contrast to similar melamine resins, benzoguanamine resins give a lower cross-link density, and thus a higher flexibility and better surface quality. Typical applications are can coatings, coil coatings, and automotive basecoats. Benzoguanamine-carboxylic acids have been proposed as cross-linkers for water-borne coatings [70].

Due to its favorable physicochemical properties, *tetra(methoxymethyl)benzoguanamine* [*4588-69-6*] has been proposed as a cross-linker for powder coatings based on hydroxy polyesters [71, 72]. However, bubbles formed during the elimination of methanol have limited its use to date.

Fully condensed formaldehyde – benzoguanamine resins that mainly consist of methylene-bridged structures are amorphous, insoluble solids with high thermal stability. Due to their high refractive index, these resins are used as white pigments or colorants in plastics [73] or, in conjunction with fluorescent dyes, as pigments for daylight fluorescent inks and paints [74, 75]. Benzoguanamine is used as a flexibilizing agent in phenolic resins to improve the punchability, water resistance, and flame-retardance of FR2-type printed circuit boards [76]. In the same way, it can be used as additive to urea – formaldehyde foams [77] or bismaleimide copolymer resins [78]. Both, acetoguanamine and benzoguanamine have been proposed as epoxy cur-

Table 5. Typical storage lifetime of formaldehyde solutions stabilized with guanamines

Formaldehyde concentration	Guanamine added	Storage temperature	Storage lifetime
40 %	0.1 % benzoguanamine	10 °C	2 weeks
40 %	0.05 % caprinoguanamine	10 °C	4 weeks
50 %	0.05 % caprinoguanamine	40 °C	4 weeks

ing agents with improved properties for microelectronic encapsulation [79, 80]. By reaction with 4,4'-diaminodiphenyl ether, benzoguanamine forms a bridged bisguanamine which was proposed for resin applications [81].

Benzoguanamine can be used instead of dichlorophenyltriazine to produce Pigment Yellow 184, an anthraquinone dye with a triazine subunit [82].

Caprinoguanamine is one of the best known stabilizers for aqueous formaldehyde solutions. It prevents or retards the precipitation of polymeric paraformaldehyde at low storage temperatures and/or high formaldehyde concentrations [83]. Though less effective, benzoguanamine is sometimes used for the same purpose. Typical stability data of aqueous formaldehyde solutions is given in Table 5.

Caprinoguanamine has been applied as additive for melamine – formaldehyde impregnation resins with improved wetting characteristics [84]. It is also used in styrenic foams to improve the foam structure and provide flame retardancy [85] (see → Flame Retardants).

Other Guanamines. Guanamines with unsaturated groups in the substituent R can also be converted to polymers and copolymers [86]. The compound "CTU" (bis-3,9-cyanoethyl-2,4,8,10-tetraoxaspiro[5.5]-undecan)-guanamine [*22535-90-6*] (formula shown below) is employed (like benzoguanamine) primarily in paints [87].

Guanamines with imidazole side chains, e.g., 2,4-diamino-6-(2′-methylimidazol-1′-yl)-ethyl-1,3,5-triazine are used as epoxy curing agents and accelerators as such or in form of adducts with, e.g., cyanuric acid [88].

Guanamine structures have also found application in pharmacology as c-AMP specific phosphodiesterase inhibitors [89], the most prominent being Irsogladine maleate (2′,5′-Dichlorobenzoguanamine, [*84504-69-8*]).

11.3. Toxicology

The acute oral LD_{50} for *acetoguanamine* in rats is 2740 mg/kg; for *benzoguanamine,* 1470 mg/kg. The corresponding value for *caprinoguanamine* is > 10 000 mg/kg, and its dermal LD_{50} (rabbit) is > 2800 mg/kg [90]. All three compounds are not irritating to skin and eyes [91, 92]. Acetoguanamine and benzoguanamine did not reveal mutagenic activity in the Ames test [93]. Long term feeding studies with benzoguanamine in male rats and mice failed to reveal carcinogenic potential [94]. Benzoguanamine was adopted by the Scientific Committee on Food as a monomer for food contact materials in List 3 with a restriction of 5 mg/kg of benzoguanamine in food [95]. The evaluation of this substance under the OECD/High Production Volume Program resulted in the conclusion, that there is low priority for further work (no further work recommended) [96].

Abstract

The article contains sections titled:

1. Introduction
1.1. Historical Development of Membranes and Membrane Processes
1.2. Advantages and Limitations of Membrane Processes
1.3. The Membrane-Based Industry
1.4. The Future of Membrane Science and Technology
2. Fundamentals
2.1. Definition of Terms
2.1.1. Definition of a Membrane and its Function
2.1.2. Definition of the Various Membrane Processes
2.1.3. The Membrane Transport Mechanism
2.2. Materials and Structures of Synthetic Membranes
2.2.1. Symmetric and Asymmetric Membranes
2.2.2. Porous Membranes
2.2.3. Homogeneous Membranes
2.2.4. Ion-Exchange Membranes
2.2.5. Liquid Membranes
2.2.6. Fixed-Carrier Membranes
2.3. Fluxes and Driving Forces in Membrane Separation Processes
2.4. Mathematical Description of Mass Transport in Membrane Processes
2.5. Membrane Separation Capability
2.6. Chemical and Electrochemical Equilibrium in Membrane Processes
2.6.1. Osmotic Equilibrium, Osmotic Pressure, Osmosis, and Reverse Osmosis
2.6.2. Donnan Equilibrium and Donnan Potential
3. Principles of Membrane Separation Processes
3.1. Principle of Microfiltration
3.2. Principle of Ultrafiltration
3.3. Principle of Reverse Osmosis
3.3.1. Mass Transport in Reverse Osmosis Described by Phenomenological Equations
3.3.2. Description of Mass Transport in Reverse Osmosis by the Solution-Diffusion Model
3.4. Principle of Gas Separation
3.4.1. Gas Separation by Knudsen Diffusion
3.4.2. Gas Transport by the Solution-Diffusion Mechanism in a Polymer Matrix
3.5. Principle of Pervaporation
3.6. Principle of Dialysis
3.6.1. Dialytic Mass Transport of Neutral Components
3.6.2. Dialytic Mass Transport of Electrolytes in a Membrane without Fixed Ions
3.6.3. Dialysis of Electrolytes in Ion-Exchange Membranes

3.7. Principle of Electrodialysis
3.7.1. Electrical Current and Ion Fluxes
3.7.2. Transport Number and Membrane Permselectivity
3.7.3. Membrane Counterion Permselectivity
3.7.4. Water Transport in Electrodialysis
3.8. Electrodialysis With Bipolar Membranes
3.9. Energy Requirements of Membrane Processes
3.9.1. Minimum Energy Required for Separation
3.9.2. Practical Energy Requirements of Membrane Processes
4. Membrane Separation Process Design and Operation
4.1. Ultrafiltration, Microfiltration, and Reverse Osmosis
4.1.1. Recovery Rate, Membrane Rejection, Retentate and Filtrate Concentrations
4.1.2. Solute Loss in Filtration
4.1.3. Effect of Osmotic Pressure on the Filtration Rate
4.1.4. Process Operating Mode
4.1.5. Diafiltration Operating Mode
4.2. Gas Separation
4.3. Pervaporation
4.4. Dialysis
4.5. Electrodialysis
4.5.1. Mass Transport in an Electrodialysis Stack
4.5.2. Energy Requirements in an Electrodialysis Desalination Process
4.5.3. Electrodialysis Process Costs
4.6. Bipolar Membrane Electrodialysis Process Design
4.6.1. Operating Modes in Bipolar Membrane Electrodialysis
4.6.2. Energy Requirements in Electrodialytic Water Dissociation
4.6.3. Total Energy Required for Production of an Acid and a Base
4.6.4. Total Process Costs
4.7. Continuous Electrodeionization Process Design
4.8. Other Membrane Processes
5. Membrane Preparation and Membrane Module Constructions
5.1. Membrane Preparation
5.1.1. Preparation of Porous Membranes
5.1.2. Preparation of Asymmetric Membranes
5.1.3. Rationalization of the Phase-Inversion Membrane Preparation Process
5.1.4. Preparation of Composite Membranes
5.1.5. Preparation of Inorganic Composite Membranes
5.1.6. Preparation of Homogeneous Solid Membranes
5.1.7. Preparation of Liquid Membranes
5.1.8. Preparation of Ion-Exchange Membranes
5.2. Membrane Characterization
5.2.1. Characterization of Porous Membranes
5.2.1.1. Membrane Separation Properties Determined by Filtration Tests
5.2.2. Characterization of Homogeneous Membranes
5.3. Membrane Modules
5.3.1. Cartridge Membrane Module
5.3.2. Plate-and-Frame Membrane Module
5.3.3. Spiral-Wound Module
5.3.4. Tubular Membrane Module
5.3.5. Capillary and Hollow-Fiber Membrane Modules
5.3.6. Other Membrane Modules
6. Concentration Polarization and Membrane Fouling
6.1. Concentration Polarization in Filtration Processes
6.1.1. Concentration Polarization without Solute Precipitation
6.1.2. Concentration Polarization with Solute Precipitation at the Membrane Surface
6.2. Membrane Fouling and its Causes
6.3. Concentration Polarization in Other Membrane Separation Processes
6.3.1. Concentration Polarization in Dialysis
6.3.2. Concentration Polarization in Electrodialysis

6.3.3. Concentration Polarization in Pervaporation
6.3.4. Concentration Polarization in Gas Separation

List of Symbols

A	m^2	surface area
a	mol m^{-3}	activity
a	–	constant
C	mol m^{-3}, mol L^{-1}	concentration
D	m	batch cell diameter
D	m s^{-1}	dialysance
D	m^2 s^{-1}	diffusion coefficient
$Đ$	m^2 s^{-1}	Stefan-Maxwell diffusion coefficient
d	m	distance
d_H	m	hydraulic diameter
d	m	stirrer length
E	A V s	energy
F	96485 A s eq^{-1}	Faraday constant
f	N s m^{-1} mol^{-1}	friction coefficient
ΔG^m	J	Gibbs free energy of mixing
g	kg m s^{-2}	acceleration
g	–	osmotic coefficient
h	m	height
I	A	current
i	A m^{-2}	current density
i_{lim}	A m^{-2}	limiting current density
J	mole m^{-2} s^{-1}	flux
K_w	mol^2 L^{-2}	water dissociation constant
k	various	coefficient
k	J mol^{-1} K^{-1}	Boltzmann constant
L	mol^2 N^{-1} m^{-2} s^{-1}	phenomenological coefficient
L_{pp}	m	process path length
M	kg mol^{-1}	molecular weight
m	m s^{-1}	mobility
N	mol s^{-1}	flux
N	–	number
n	–	number of moles
P	mol m^{-1} s^{-1} J^{-1}	permeability
p	Pa	pressure
Q	m^3 s^{-1}	volume flux
R	Ω	electrical resistance
R	J mol^{-1} K^{-1}	gas constant
R	–	rejection
R_m	N m s^{-1}	membrane resistance
r	Ω m^2	area resistance
r	N s^{-1}	specific resistance
r	m	radius
Re	–	Reynolds number
S	–	permselectivity
Sc	–	Schmidt number
Sh	–	Sherwood number

T	K	temperature
T	–	transport number
t	s	time
U	V	electrical potential
u	$m^2\ s^{-1}\ V^{-1}$	ion mobility
u	$m\ s^{-1}$	velocity
V	m^3	volume
$\bar{V}$	$m^3\ mol^{-1}$	partial molar volume
v	$m\ s^{-1}$	velocity
w	m	width
X	m	cell length
X	$Nm\ mol^{-1}$	driving force
X	–	mole fraction
x	m	directional co-ordinate
Y	m	cell width
Z_b	μ	boundary layer thickness
z	m	directional coordinate
z	$eq\ mol^{-1}$	valence

Greek letters

α	–	separation factor
α	–	dissociation degree
β	–	enrichment factor
γ	$m^3\ mol^{-1}$	activity coefficient
Δ	m	cell thickness
Δ	–	difference
Δ	–	recovery rate
δ	–	fractional product loss
ε	–	porosity
η	$kg\ m^{-1}\ s^{-1}$	dynamic viscosity
η	$A\ V\ s\ mol^{-1}$, $J\ mol^{-1}$	electrochemical potential
θ	–	stage cut
κ	$\Omega^{-1}\ m^{-1}$	specific conductivity
Λ_{eq}	$m^2\ \Omega^{-1}\ eq^{-1}$	electrolyte equivalent conductivity
λ	m	distance
λ	$m^2\ \Omega^{-1}\ eq^{-1}$	ion equivalent conductivity
μ	$J\ mol^{-1}$	chemical potential
ν	$m^2\ s^{-1}$	kinematic viscosity
ν	–	stoichiometric coefficient
ξ	–	current utilization
π	Pa, $N\ m^{-2}$	osmotic pressure
ρ	$kg\ m^{-3}$	density
ρ	Ω m	specific resistance
σ	$mol\ N^{-1}\ s^{-1}$	reflection coefficient
σ	$N\ m^{-1}$	surface tension
τ	–	tortuosity factor
φ	°	contact angle
φ	V	electrical potential
φ	–	fugacity coefficient
ϕ	–	pressure ratio
Ψ	$N\ m\ s^{-1}$	dissipation function
Ψ	–	membrane permselectivity
ω	s^{-1}	circular velocity
ω		

	mol m^{-1}	permeability
ω	–	porosity

Subscripts

A	component
a	anion

1. Introduction

The separation, concentration, and purification of molecular mixtures are major problems in the chemical industries. Efficient separation processes are also needed to obtain high-grade products in the food and pharmaceutical industries, to supply communities and industry with high-quality water, and to remove or recover toxic or valuable components from industrial effluents. For this task a multitude of separation techniques such as distillation, precipitation, crystallization, extraction, adsorption, and ion exchange are used today. More recently, these conventional separation methods have been supplemented by a family of processes that utilize semipermeable membranes as separation barriers. Membranes and membrane processes were first introduced as an analytical tool in chemical and biomedical laboratories, and they developed very rapidly into industrial products and methods with significant technical and commercial impact [1, 2]. Today, membranes are used on a large scale to produce potable water from seawater, to clean industrial effluents and recover valuable constituents, to concentrate, purify, or fractionate macromolecular mixtures in the food and drug industries, and to separate gases and vapors. They are also key components in energy conversion and storage systems, artificial organs, and drug delivery devices.

The membranes used in the various applications differ widely in their structure, their function, and the way they are operated in a separation process. However, all membranes and membrane processes share several features that make them particularly attractive tools for the separation of molecular mixtures. The separation is performed by physical means at ambient temperature without chemically altering the constituents. This is important for applications in artificial organs and in many drug delivery systems, as well as in the food and drug industries or in downstream processing of bioproducts where temperature-sensitive substances must often be handled. Furthermore, membrane properties can be tailored and adjusted to specific separation tasks, and membrane processes are often technically simpler and more energy efficient than conventional separation techniques and are equally well suited for large-scale continuous operations as for batchwise treatment of very small quantities.

A key property of a membrane is its permselectivity, which is determined by differences in the transport rate of various components through the membrane. The transport rate of a component through a membrane is determined by the structure of the membrane, the size of the permeating component, by the chemical nature and the electrical charge of the membrane material and permeating component, and by the driving force due to the chemical or electrochemical potential gradients, that is, concentration pressure and electrical potential differences. Some driving forces such as concentration, pressure, and temperature gradients act equally on all components, in contrast to an electrical potential as driving force, which is only effective with charged components. The use of different membrane structures and driving forces has resulted in a number of rather different membrane processes such as reverse osmosis, micro- and ultrafiltration, dialysis, electrodialysis, Donnan dialysis, pervaporation, gas separation, and so on. The versatility of membrane structures and functions makes a precise and complete definition of a membrane rather difficult. In the most general sense a membrane can be described as a barrier that separates two different regions and controls the exchange of matter, energy, and information between the regions in a very specific way. The term “membrane” describes two very different items, that is, biological membranes, which are part of a living organism, and synthetic membranes, which are man-made. Biological membranes carry out very complex and specific transport tasks in organisms. They accomplish them quickly, efficiently, and with minimal energy expenditure, often utilizing carrier-facilitated and active transport coupled to a chemical reaction. Synthetic membranes are not nearly as complex in their structure or function as biological membranes. They are usually less selective and energy-efficient but have significantly higher chemical, thermal, and mechanical stability. In practical separation processes biological membranes have no significance today and will therefore not be discussed in this article. Because membranes are capable of separating molecular mixtures very selectively and efficiently at room temperature by physical means their potential applications are extremely wide compared to conventional separation processes. Today membranes are used on a large technical scale in three distinct areas: The first area includes applications in which the use of membranes is technically feasible, but where they must compete with conventional separation processes on the basis of overall economy. This, for instance, is the case in seawater desalination and the treatment of certain wastewater streams. Here, membranes must compete with distillation and biological treatment, respectively. The second area includes applications for which alternative techniques are available, but membranes offer a clear technical and commercial advantage. This is the case in the production of ultrapure water and in the separation of certain food products. Finally, there are applications where there is no reasonable alternative to membrane processes. This is the case in certain drug delivery systems and artificial organs.

1.1. Historical Development of Membranes and Membrane Processes

Synthetic membranes are a rather recent development and the technical utilization of membrane processes on a large scale began just 40 years ago. The first recorded study of membrane phenomena and the discovery of osmosis dates back to NOLLET, who discovered in 1748 [3] that a pig's bladder passed preferentially ethanol when it was brought in contact on one

side with a water – ethanol mixture and on the other side with pure water. NOLLET was probably the first to recognize the relation between a semipermeable membrane, osmotic pressure, and volume flux. More systematic studies on mass transport in semipermeable membranes were carried out by GRAHAM [4] in 1833, who studied the diffusion of gases through different media and discovered that rubber exhibits different permeabilities to different gases. Most of the early studies on membrane permeation were carried out with natural materials such as animal intestines, bladders, and gum elastics. In 1867 TRAUBE [5] was the first to introduce an artificially prepared semipermeable membrane by precipitating cupric ferrocyanide in a thin layer of porous porcelain. This type of membrane was used by PFEFFER [6] in his fundamental studies on osmosis. However, the theoretical treatment and much of the interpretation of osmotic phenomena and mass transport through membranes is based on the studies of FICK [7] in 1877, who interpreted diffusion in liquids as a function of concentration gradients, and those of VAN T' HOFF [8] in 1887, who gave a thermodynamic explanation for the osmotic pressure of dilute solutions. Later NERNST [9] in 1889 and PLANCK [10] in 1890 introduced the flux equation for electrolytes under the driving force of a concentration or electrical potential gradient. With the classical publications of DONNAN [11] in 1911, describing the theory of membrane equilibria and membrane potentials in the presence of electrolytes, the early history of membrane science ends with most of the basic phenomena satisfactorily described and theoretically interpreted. With the beginning of the 1900s membrane science and technology entered a new phase. First, BECHHOLD [12] developed in 1908 a method of making the first synthetic membranes by impregnating a filter paper with a solution of nitrocellulose in glacial acetic acid. These membranes could be prepared and accurately reproduced with different permeabilities by varying the ratio of acetic acid to nitrocellulose.

Nitrocellulose membranes were also used in the studies of ZSIGMONDY and BACHMANN [13] in 1918 as ultrafilters to separate macromolecules and fine particles from an aqueous solution. These studies were later continued by many others, including ELFORD [14] in 1930, and MCBAIN and KISTLER [15] in 1931. The relation between the streaming potential, electroosmosis, and electrodialysis was treated in 1931 in a monograph of PRAUSNITZ and REITSTÖTTER [16]. Based on a 1922 patent of ZSIGMONDY [17], Sartorius GmbH in Germany began in 1937 the production of a series of nitrocellulose membranes with various pore sizes. These membranes were used in microbiological laboratories in analytical applications. The development of the first successfully functioning hemodialyzer by KOLFF and BERK [18] in 1944 was the key to the large-scale application of membranes in the biomedical area. All synthetic membranes available up to that time were microporous structures separating mixtures exclusively according to their size. In the early days of membrane science and technology membranes had been mainly a subject of scientific interest with only a very few practical applications. This changed drastically from 1950 on, when the practical use of membranes in technically relevant applications became the main focus of interest and a significant membrane-based industry developed rapidly. Progress in polymer chemistry resulted in a large number of synthetic polymers which ultimately became available for the preparation of new membranes with specific transport properties plus excellent mechanical and thermal stability. Membrane transport properties were described by a comprehensive theory based on the thermodynamics of irreversible processes by STAVERMAN [19] in 1952, KEDEM and KATCHALSKY [20], SCHLÖGL [21], and SPIEGLER [22] in 1961. A second route for describing membrane processes was based on postulating certain membrane transport models, such as the model of a diffusion-solution membrane by MERTEN [23] in 1966. The properties of ion-exchange membranes were studied extensively by HELFFERICH [24] in 1962 and many others.

A milestone in membrane science and technology was the development of a reverse osmosis membrane based on cellulose acetate which provided high salt rejection and high fluxes at moderate hydrostatic pressures by REID and BRETON [25] in 1959 and LOEB and SOURIRAJAN [26] in 1962, which were major advances toward the application of reverse osmosis membranes as an effective tool for the production of potable water from seawater.

The membrane developed by LOEB and SOURIRAJAN had an asymmetric structure with a dense skin at the surface, which determined the membrane selectivity and flux, and highly porous substructure, which provided the mechanical strength. It was shown by KESTING [27] in 1971 that the preparation of asymmetric cellulose acetate membrane was based on a phase inversion process in which a homogeneous polymer solution is converted into a two-phase system, that is, a solid polymer-rich phase providing the solid polymer structure and a polymer-lean phase forming the liquid-filled membrane pores. STRATHMANN et al. [28] rationalized in 1971 the formation mechanism of asymmetric membranes and correlated different structures with the various preparation parameters. Soon, other synthetic polymers such as polyamides, polyacrylonitrile, polysulfone, and polyethylene were used as basic materials for the preparation of synthetic membranes. These polymers often showed better mechanical strength, chemical stability, and thermal stability than the cellulose esters. However, cellulose acetate remained the dominant material for the preparation of reverse osmosis membranes until the development of the interfacial-polymerized composite membrane by CADOTTE [29] and independently by RILEY [30] in 1980. These membranes showed significantly higher fluxes, higher rejection, and better chemical and mechanical stability than the cellulose acetate membranes.

The first membranes developed for reverse-osmosis desalination and other applications were manufactured as flat sheets and then installed in a so-called spiral-wound module, based on the work of BRAY [31] and WESTMORELAND [32] in 1982. A different approach to membrane geometry was taken in the early 1960s by MAHON [33], who made self-supporting hollow-fiber membranes with a wall thickness of only 6 – 7 µm. However, the permeate flux was rather low, presumably because the fibers were isotropic in structure. This problem was overcome later by Du Pont Corporation, which made an asymmetric hollow-fiber membrane with main application in desalination of brackish and seawater.

Soon after the development of efficient membranes, appropriate membrane housing assemblies, called modules, were devised. The criteria for the design of such modules included high membrane packing density, reliability, ease of membrane or module replacement, control of concentration polarization, and low cost. Membranes were produced in three different configurations: as flat sheets, as hollow fine fibers or capillaries, and as tubes. In modern reverse-osmosis desalination plants mainly spiral-wound modules are used, while hollow-fiber membrane modules are utilized in gas separation and pervaporation. In medical applications such as artificial kidneys and blood oxygenators, capillary membranes play a dominant role today. Tubular membranes are mainly used in micro- and ultrafiltration.

Even earlier than the large-scale use of reverse osmosis for desalination of sea- and brackish water was the industrial-scale application of electrodialysis. The history of electrodialysis goes back to the work of MEYER and STRAUSS [34], who developed the first multicell stack just before World War II. However, modern electrodialysis became a practical reality with

the work of JUDA and MCRAE [35] in 1953, who developed the first reliable ion-exchange membranes having both good electrolyte conductivity and ion permselectivity. Electrodialysis was first commercially exploited for the desalination of brackish water by Ionics Inc. The commercial success of Ionics was due to their membranes, their compact stacking, and the mode of operation referred to as electrodialysis reversal, which provided a periodic self-cleaning mechanism for the membrane stack and thus allowed long-term continuous operation at high concentrations of scaling materials without mechanical cleaning of the stack [36].

While Ionics pioneered the development of electrodialysis for water desalination a completely different use of electrodialysis was envisioned in Japan. Here, electrodialysis was used for concentrating sodium chloride solutions from seawater to produce table salt, as described by NISHIWAKI [37]. In the early 1980s a completely new area for the application of electrodialysis was opened up. At this time LIU et al. [38] introduced bipolar membranes for the recovery of acids and bases from the corresponding salts by water dissociation induced by an electrical potential.

The large-scale separation of gases and vapors is also a relevant industrial area for membrane applications. Gas separation was pioneered by HENIS and TRIPODI [39] in 1981. Originally, the aim was to recover hydrogen from off-gases and to produce oxygen- or nitrogen-enriched air. Today, however, a large number of other applications such as the removal of CO_2 from natural gas and the recovery of organic vapors from off-gases are typical applications for gas and vapor separation. Pervaporation, which in its basic principle is closely related to vapor separation, was studied extensively by APTEL and NEEL [40] in 1968, who pointed out a large number of interesting potential applications, but so far very few large commercial plants have been built.

Other applications of membranes which were developed in more recent years and have reached major technical and commercial significance include the controlled release of drugs in therapeutic devices and the storage and conversion of energy in fuel cells and batteries.

1.2. Advantages and Limitations of Membrane Processes

In many applications membrane processes compete directly with the more conventional techniques. However, compared to these conventional procedures membrane processes are often more energy efficient, simpler to operate, and yield higher quality products. Furthermore, the environmental impact of all membrane processes is relatively low. There are no hazardous chemicals used in the processes that have to be discharged and there is no heat generation. However, there are certain limitations to the application of membrane processes. A major disadvantage of membranes, especially in water- and wastewater-treatment processes, is that until today the long-term reliability has not completely been proven. Membrane processes sometimes require excessive pretreatment due to their sensitivity to concentration polarization, chemical interaction with water constituents, and fouling. Membranes are mechanically not very robust and can easily be destroyed by a malfunction in the operating procedure. Another critical issue are the process costs. In general, membrane processes are quite energy efficient. However, the energy consumption is only part of the total process costs. Other factors determining the overall economics of a process include the investment-related cost, which is determined by the cost of the membranes and other process equipment and their useful life under operating conditions, and various pre- and post-treatment procedures of the feed solutions and the products. Plant capacity may also play a role in total cost. While, for example, in distillation processes usually a substantial cost reduction can be achieved with an increase in the plant capacity, the scale-up factor has only a relatively small effect on the process cost in desalination of water by reverse osmosis or electrodialysis. Depending on the composition of the feed solution and the required quality of the product water, a combination of processes may be appropriate. For example, if ultrapure water for certain industrial applications is required, a sequence of processes may be applied, such as reverse osmosis, ion exchange, UV sterilization, and microfiltration as a point-of-use-filter to remove traces of particles.

The environmental impact of all membrane processes is relatively low. There are no hazardous chemicals used in membrane processes which have to be discharged. In certain applications such as the purification of industrial effluents and wastewaters or the desalination of brackish water there may be a problem with the disposal of the concentrate. In these applications brine post-treatment procedures may be necessary.

1.3. The Membrane-Based Industry

Parallel to the development of membranes and membrane processes was the development of a membrane-based industry. The structure of this industry is quite heterogeneous as far as the size of the companies and their basic concept towards the market is concerned. Several companies have concentrated on the production of membranes only. Membrane producers are frequently divisions of major chemical companies. They offer a range of membrane products as flat sheets, hollow fibers, or capillaries with different properties and for different applications ranging from seawater desalination and hemodialysis to purification of wastewater and fuel cells. Other companies buy membranes or modules as key components from one or several membrane manufacturers, design and build the actual plant, and often also operate it, guaranteeing the customer a certain amount of product of a given quality. Sometimes, these companies provide different processes, such as reverse osmosis, nanofiltration, and electrodialysis according to the requirements of the separation task. These companies provide a solution to a customer's separation problem in general, which might be a combination of separation processes such as ion exchange, carbon adsorption, flocculation and precipitation, or various chemical and biological treatment procedures in addition to membrane processes. Although the sales of membranes and membrane modules to any one of these companies are often not very large they are of importance in the membrane industry because of their specific application know-how in different markets. Finally, there are companies that provide the membranes, the system or product design, and the operation of the process. The companies concentrate very often on a single, usually very large application such as production of potable water from sea- or brackish water or hemodialysis. They often not only provide the tools for producing potable water in the case of seawater desalination, but also operate the plant and distribute the water. Companies producing artificial kidneys also operate dialysis stations. The membrane market is characterized by a few rather large market segments, such as sea- and brackish-water desalination, production of ultrapure water, and hemodialysis and a large number of small market segments in the food, chemical, and pharmaceutical industries, analytical laboratories, and especially in the treatment and recycling of industrial wastewater streams. The larger markets for water desalination and hemodialysis are dominated by a relatively small number of large companies. A multitude of small companies are active in market niches such as treating

certain wastewater streams or providing services to the chemical or food and drug industries.

1.4. The Future of Membrane Science and Technology

In many applications today's membranes and processes are quite satisfactory, while in other applications there is a definite demand for further improvements of both membranes and processes. For desalination of sea- and brackish water by reverse osmosis, for example, there are membranes available today that are quite satisfactory as far as flux and salt rejection are concerned, and the processes have been proven by many years of operating experience. The same is true for hemodialyzers and hemofiltration. In these applications only marginal improvements can be expected in the near future. In micro- and ultrafiltration and electrodialysis the situation is similar. The properties of current membranes are satisfactory. However, there are other components such as the process design, application know-how, and long-term operating experience that are of importance in the use of micro- and ultrafiltration in the chemical and food industries and in wastewater treatment. Here, concentration polarization and membrane fouling play a dominant role, and new membrane modules and process design concepts which provide a better control of membrane fouling and thus result in a longer useful life of the membranes are highly desirable. In other membrane processes such as gas separation, pervaporation, fuel cell separators, and membrane reactors, the situation is quite different. Here, better membranes, improved process design and extensive application know-how and long-term experience are mandatory to establish membrane processes as a proven and reliable technology.

[Top of Page]

2. Fundamentals

Membrane processes such as dialysis, electrodialysis, reverse osmosis, and micro- and ultrafiltration differ widely as far as the applied membrane structures and the driving forces for mass transport are concerned. There are, however, some common fundamentals, such as certain thermodynamic and kinetic relations describing mass transport in membranes and at the membrane/bulk solution interface. Phenomena such as concentration polarization and membrane fouling occur in all membrane processes and have common causes and consequences. Thus, before treating the different membrane processes and their application in more detail, some common fundamentals are discussed.

2.1. Definition of Terms

The performance of membrane processes in a certain application is determined by a number of components and process parameters such as the membranes, the membrane modules, the driving forces applied to achieve the desired mass transport and certain chemical engineering aspects relevant for designing processes. These components and process parameters and their function must be defined.

2.1.1. *Definition of a Membrane and its Function*

A precise and complete definition of a membrane that covers all its aspects is rather difficult, even when the discussion is limited to synthetic structures as in this article. In the most general sense, a synthetic membrane is an interphase that separates two phases and restricts the transport of various components in a specific manner [1]. A membrane can be homogeneous or heterogeneous, symmetric or asymmetric in structure. It may be solid or liquid and may consist of organic or inorganic materials. It can be neutral or can carry positive or negative charges, or functional groups with specific binding or complexing abilities. Its thickness can be less than 100 nm or more than one millimeter. The electrical resistance may vary from more than $10^6\ \Omega\ cm^2$ to less than $1\ \Omega\ cm^2$. The term “membrane” therefore includes a great variety of materials and structures, and a membrane can often be better described by its function rather than by its structure. Some materials, such as protective coatings, or packaging materials, though not meant to be membranes, show typical membrane properties, and are in fact membranes. All materials functioning as membranes have one characteristic property in common: They restrict the passage of different components in a very specific manner. Separation of a mixture in a membrane process is the result of different transport rates of different components through the membrane. The transport rate of a component through a membrane is determined by driving forces such as concentration, pressure, temperature, and electrical potential gradients, and the concentration and mobility of the component in the membrane matrix.

2.1.2. *Definition of the Various Membrane Processes*

Membrane processes can be grouped according to the applied driving forces into pressure-driven processes such as reverse osmosis or ultra- and microfiltration, concentration gradient driven processes such as dialysis and Donnan dialysis, and electrical potential driven processes such as electrodialysis. The molecular mixture to be separated is referred to as feed, the mixture containing the components retained by the membrane is called the retentate, and the mixture composed of the components that have permeated the membrane is referred to as permeate or filtrate in micro- and ultrafiltration.

2.1.3. *The Membrane Transport Mechanism*

The mechanism by which certain components are transported through a membrane can also be very different. In some membranes, for example, the transport is based on viscous flow of a mixture through individual pores in the membrane caused by a hydrostatic pressure difference between the two phases separated by the membrane. This type of transport is referred to as viscous flow. It is the dominant form of mass transport in micro- and ultrafiltration but also occurs in other membrane processes. If the transport through a membrane is based on the dissolution and diffusion of individual molecules in the membrane matrix due to a concentration or chemical potential gradient the transport is referred to as diffusion. This form of mass transport is dominant in reverse osmosis, gas separation, pervaporation, and dialysis but may occur in other processes, too. If an electrical potential gradient across the membrane is applied to achieve the desired transport of certain components through the membrane the transport is referred to as migration. Migration occurs in electrodialysis and related processes and is limited to the transport of components carrying electrical charges, such as ions.

2.2. Materials and Structures of Synthetic Membranes

Synthetic membranes show a large variety in their physical structure and the materials they are made from. Based on their structure they can be classified into four groups:

- Porous membranes
- Homogeneous solid membranes
- Solid membranes carrying electrical charges
- Liquid or solid films containing selective carriers

Furthermore, the structure of membranes may be symmetric, that is, the structure is identical over the entire cross section of the membrane, or it may be asymmetric, that is, the structure varies over the cross section of the membrane.

The materials used for the preparation of membranes can be polymers, ceramics, glass, metals, or liquids. The materials may be neutral or carry electrical charges (i.e., fixed ions). The schematic in Figure 1 illustrates the morphology and materials of some technically relevant synthetic membranes.

Figure 1. Schematic illustrating the various materials and structures of technically relevant synthetic membranes

2.2.1. *Symmetric and Asymmetric Membranes*

As indicated earlier synthetic membranes may have a symmetric or an asymmetric structure. In a symmetric membrane the structure and the transport properties are identical over the entire cross section, and the thickness of the entire membrane determines the flux. Symmetric membranes are used today mainly in dialysis and electrodialysis. In asymmetric membranes structural and transport properties vary over the membrane cross section. An asymmetric membrane consists of a 0.1 – 1 µm thick “skin” layer on a highly porous 100 – 200 µm thick substructure. The skin represents the actual selective barrier of the asymmetric membrane. Its separation characteristics are determined by the nature of the material or the size of its pores. The mass flux is determined mainly by the skin thickness. The porous sublayer serves only as a support for the mostly thin and fragile skin and has little effect on the separation characteristics or the mass transfer rate of the membrane. Asymmetric membranes are used primarily in pressure-driven membrane processes such as reverse osmosis, ultrafiltration, and gas and vapor separation, since here the unique properties of asymmetric membranes, that is, high fluxes and good mechanical stability, can best be utilized. Two techniques are used to prepare asymmetric membranes: one utilizes the phase-inversion process, which leads to an integral structure with the skin and the support structure made from the same material in a single process [27], and the other resembles a composite structure where a thin barrier layer is deposited on a porous substructure in a two-step process [29]. In this case barrier and support structures are generally made from different materials.

2.2.2. *Porous Membranes*

A porous structure represents a very simple form of a membrane, which closely resembles the conventional fiber filter as far as the mode of separation is concerned. These membranes consist of a solid matrix with defined holes or pores which have diameters ranging from less than 1 nm to more than 10 µm. Separation of the various components is achieved strictly by a sieving mechanism with the pore diameters and the particle sizes being the determining parameters. Porous membranes can be made from various materials such as ceramics, graphite, metals, metal oxides, and various polymers. Their structure can be symmetric, that is, the pore diameters do not vary over the membrane cross section, or asymmetric, that is, the pore diameters increase from one side of the membrane to the other, typically by a factor of 10 to 1000. The techniques for the preparation of porous membranes can be rather different and include simple pressing and sintering of polymer or ceramic powders, irradiation and leaching of templates, as well as phase-inversion and polymer-precipitation procedures or sol – gel conversion techniques. Porous membranes are used to separate components that differ markedly in size or molecular weight in processes such as micro- and ultrafiltration or dialysis [41].

2.2.3. *Homogeneous Membranes*

A homogeneous membrane is merely a dense film through which a mixture of molecules is transported by a pressure, concentration, or electrical potential gradient. The separation of the various components of a mixture is directly related to their transport rates within the membrane phase, which is determined by their diffusivities and concentrations in the membrane matrix. Therefore, homogeneous membranes are referred to as solution – diffusion-type membranes [23]. They can be prepared from polymers, metals, metal alloys, and, in some cases, ceramics, which may also carry positive or negative electrical charges. Since the mass transport in homogeneous membranes is based on diffusion, their permeabilities are rather low. Homogeneous membranes are used mainly to separate components which are similar in size but have different chemical nature in processes such as reverse osmosis, gas and vapor separation, and pervaporation [42]. In these processes asymmetric membrane structures are used which consist of a thin homogeneous skin supported by a porous substructure.

2.2.4. *Ion-Exchange Membranes*

Films carrying charged groups are referred to as ion-exchange membranes. They consist of highly swollen gels carrying fixed positive or negative charges. The properties and preparation procedures of ion-exchange membranes are closely related to those of ion-exchange resins [24]. There are two different types of ion-exchange membranes: 1) cation-exchange membranes, which contain negatively charged groups fixed to the polymer matrix, and 2) anion-exchange membranes, which contain positively charged groups fixed to the polymer matrix. In a cation-exchange membrane, the fixed anions are in electrical equilibrium with mobile cations in the interstices of the polymer. In contrast, the mobile anions are more or less completely excluded from the cation-exchange membrane because of their electrical charge, which is identical to that of the fixed ions. Due to this exclusion of the anions, a cation-exchange membrane permits transfer of cations only. Anion-exchange membranes carry positive charges fixed on the polymer matrix. Therefore, they exclude all cations and are permeable only to anions. Although there are a number of inorganic ion-exchange materials, mostly based on zeolites and bentonites, these materials are rather unimportant in ion-exchange membranes compared to polymer materials [24]. The main applications of ion-exchange membranes are in electrodialysis and electrolysis. They are also used as ion-conducting separators in batteries and fuel cells.

2.2.5. *Liquid Membranes*

Liquid membranes are mainly used in combination with the so-called facilitated transport which is based on “carriers” which transport certain components such as metal ions selectively across the liquid membrane interphase. Generally, it is no problem to form a thin fluid film. It is difficult, however, to maintain and control this film and its properties during a mass separation process. To avoid breakup of the film, some type of reinforcement is necessary to support such a weak membrane structure. Two different techniques are used today for the preparation of liquid membranes. In the first, the selective liquid barrier material is stabilized as a thin film by a surfactant in an emulsion-type mixture [43]. In the second, a porous structure is filled with the liquid membrane phase. Both types of membranes are used today on a pilot-plant scale for the selective removal of heavy metal ions or certain organic solvents from industrial waste streams [44]. They have also been used rather effectively for the separation of oxygen and nitrogen.

2.2.6. *Fixed-Carrier Membranes*

Fixed-carrier membranes consist of a homogeneous or porous structure with functional groups which selectively transport certain chemical compounds. Fixed-carrier membranes can have a symmetric or asymmetric structure depending on their application. They are used today, for example, in co- and countercurrent transport and in the separation of alkane – alkene mixtures.

2.3. Fluxes and Driving Forces in Membrane Separation Processes

Separation in membrane processes is the result of differences in the transport rates of different chemical species through the membrane. The transport rate is determined by the driving force or forces acting on the individual components and their mobility and concentration in the membrane. The mobility of a component in the membrane is primarily determined by its size and the physical structure of the membrane material, while the concentration of the solute in the membrane is primarily determined by the chemical compatibility of the permeating component and the membrane material. In membrane separation processes there are different forms of mass transport as indicated in Figure 2, which show schematically the mass transport through membranes separating two homogeneous phases.

In the most general form mass transport through a membrane is shown in Figure 2a, in which the membrane acts as barrier that restricts the flux of various components due to their chemical nature, size, or electrical charge. The transport of a component A is caused by a driving force across the membrane acting on this component. The driving force is a difference in energy of the component A in the two phases separated by the membrane. Thus, the driving force for the transport of a component through a membrane can be expressed in a very general form by the energy gradient, that is, the gradient in its electrochemical potential across the membrane. Gradients in the electrochemical potential of a component are the result of hydrostatic pressure, concentration, electrical potential, or temperature differences between the two phases separated by the membrane [46].

Figure 2. Schematic illustrating various modes of mass transport in membranes

In the example illustrated in Figure 2a it is assumed that the membrane is just a passive physical barrier without specific interactions between the permeating components and the membrane matrix. If the transport of certain components is facilitated due to specific interactions with a carrier component in the membrane matrix the process is referred to as facilitated transport. There are two types of membranes with carrier-facilitated transport properties. The first type is a membrane with the carriers fixed to the membrane matrix where the transported component moves through the membrane by “hopping” from one carrier site in the membrane to the next [45]. The second type is a liquid membrane with the mobile carrier dissolved in a liquid film. The process i illustrated in Figure 2b. Here, the transported components are coupled to the carrier on one side of the membrane, that is, the side facing the feed solution. Then they are transported through the membrane coupled to the carrier by diffusion. This facilitated transport is generally more selective than transport through a passive membrane. However, to achieve a flux of a component an electrochemical potential gradient is also required in a membrane with facilitated transport properties.

There may also be a coupling of the fluxes of individual components. One example of the coupling of fluxes is the transport of bound water with an ion which is transported across a membrane by an electrical potential gradient. More important in membrane processes is the coupling of ion fluxes which results when electrically charged components have different permeability in a membrane. Here, the coupling of fluxes is the result of the electroneutrality condition, which requires that on a macroscopic scale there is no excess of electrical charges. If there is no electrical current, positively or negatively charged components can only be transported across a membrane when the same number of opposite charges carried by counterions are transported in the same direction, or if components with the same charges carried by co-ions are transported in the opposite direction. Thus two forms of flux coupling can be distinguished: cocurrent coupled transport when co- and counterion are transported in the same direction, and countercurrent coupled transport when no counterions permeate the membrane and co-ion fluxes are in opposite direction. The transport of various ions through a membrane by coupling with co- or counterions is illustrated in Figure 3.

Figure 3. Schematic illustrating a) cocurrent and b) countercurrent coupled transport

In the cocurrent transport shown schematically in Figure 3a component A^- is an anion, and B^+ and C^+ are cations. The concentrations of the components A^- and B^+ in phase′ is higher than in phase″ and the concentration of the component C^+ in phase′ is lower than that in phase″. It is assumed that the membrane is an anion-exchange membrane and thus permeable for the anion A^-. Cation C^+ can permeate the membrane only by means of a specific carrier, and the cation B^+ can not permeate the membrane at all. Due to the concentration differences of the components in the two phases there is a strong driving force for anion A^- to permeate through the membrane from phase′ into phase″. However, because of the electroneutrality requirement it must be accompanied by a cation. The only cation capable of permeating the membrane due to a specific carrier is C^+, which will be transported against its chemical potential gradient from a lower concentration in phase′ to a higher concentration in phase″.

In the countercurrent coupled transport illustrated in Figure 3b a negatively charged cation-exchange membrane separates phase′ and phase″. The concentration of all components in phase′ is assumed to be higher than that in phase″. Thus, there is a driving force for all components to permeate the membrane from phase′ into phase″. Since anion A^- can not permeate the cation-exchange membrane, cation C^+ can only move from phase′ into phase″ if the same number of electrical charges of component B^+ are transported in the opposite direction against its concentration gradient. Both cocurrent coupled transport, which is usually referred to as diffusion dialysis, and countercurrent coupled transport, which is also called Donnan dialysis, are of practical relevance in wastewater treatment.

2.4. Mathematical Description of Mass Transport in Membrane Processes

Mass transfer in membrane processes is determined by the driving forces acting on the individual components in the membrane and by the friction which the components must overcome when moving through the membrane matrix. The driving forces acting on the components of a system can be expressed by gradients in their electrochemical potential and by a hydrostatic pressure gradient causing a bulk volume flow. The friction that must be overcome by the driving force or forces to achieve the transport of the component is generally expressed by a hydrodynamic permeability coefficient, a diffusion coefficient, or, in electrolyte solutions, also by the electrical resistance. To describe the mass transport through a membrane the thermodynamic (i.e., driving forces) and kinetic parameters (i.e., the friction coefficients) must be mathematically related.

In the most general form the mass transport through a membrane can be described by:

$$J_i = -P_i \frac{\mathrm{d}\,X_i}{\mathrm{d}\,z} \tag{2.1}$$

where J is the flux, P a general permeability coefficient, gradient $\mathrm{d}X/\mathrm{d}z$ represents the driving force, and subscript i refers to a component.

The driving force for the transport of a component through the membrane can be expressed by the gradient of its electrochemical potential in the membrane matrix, which is given by:

$$\mathrm{d}\,X_i = \mathrm{d}\,\eta_i = \mathrm{d}\,\mu_i + z_i F \mathrm{d}\,\varphi = \overline{V}_i \mathrm{d}\,p + RT\mathrm{d}\,\ln\,a_i + z_i F \mathrm{d}\,\varphi \tag{2.2}$$

where $\mathrm{d}\,\eta$ and $\mathrm{d}\,\mu$ are the gradients in the electrochemical and the chemical potential; $\mathrm{d}p$, $\mathrm{d}a$, and $\mathrm{d}\,\varphi$ the pressure, the activity, and electrical potential gradients across the membrane; $\overline{V}$ is the partial molar volume; F the Faraday constant; R the gas constant; z the charge number, which is also referred to as the valence of a charged component; and subscript i refers to component i.

In the most general form the flux of a component through a membrane can be described by inserting Equation (2.2) into Equation (2.1):

$$J_i = -P_i \frac{\mathrm{d}}{\mathrm{d}\,z}\left(\overline{V}_i \mathrm{d}\,p + RT\,\ln\,a_i + z_i F \mathrm{d}\,\varphi\right) \tag{2.3}$$

Equation (2.3) describes the flux of a component i through a membrane in reference to any other component in the membrane. If the membrane is used as frame of reference and there is convective flow, for example, through defined membrane pores this convective flow must be taken into account and an additional term must be added in Equation 2.3:

$$J_i = -P_i \frac{\mathrm{d}}{\mathrm{d}\,z}\left(\overline{V}_i \mathrm{d}\,p + RT\ln a_i + z_i F \mathrm{d}\,\varphi\right) + J_v C_i \tag{2.4}$$

where J_v is the convective flux in a membrane pore, and C_i the concentration of component i in the solution or mixture permeating the membrane by convective flow.

Note that the gradient of the chemical or electrochemical potential always refers to the membrane phase. It is usually assumed that the membrane phase is in equilibrium with the adjacent outside phases, that is, the electrochemical potentials

in the membrane η^m and in the adjacent phase η' are identical. This, however, is not true for the concentration of a component, which in the membrane is often very different from that in the adjacent phase. The concentration in the membrane is related to that in the adjacent phase by:

$$C^m = k\,C' \tag{2.5}$$

where *k* is a distribution coefficient of a component between an outside phase and the membrane matrix, which in homogeneous polymer membranes is identical with the solubility coefficient. Equations (2.3) and (2.4) are complete but rather complex descriptions of the transport of a component through a membrane in which three different additive forms of transport can be distinguished, that is, convection, diffusion, and migration.

Convection is a movement of mass due to a mechanical force, generally a hydrostatic pressure difference. Convective transport is generally less important in homogeneous solid materials such as ion-exchange membranes. It is, however, dominant in porous structures and stirred solutions.

Diffusion is a flux of molecular components due to a local gradient in the chemical potential. Gradients in the chemical potential of a component under isothermal conditions can arise from gradients in concentration or pressure. The dominant term for molecules or ions transported through an ion-exchange membrane or in a solution by diffusion is the concentration gradient. For the diffusion of ions it is mandatory that the electroneutrality requirement is fulfilled, that is, cations and anions have to diffuse in the same direction.

Migration is a movement of ions due to an electrical potential gradient. An electrical potential gradient is usually established by applying a voltage difference between two electrodes dipping into an electrolyte solution. The positively charged cations migrate towards the negatively charged cathode and the negatively charged anions migrate towards the positively charged anode, that is, cations and anions are transported in opposite directions.

Convection, diffusion, and migration are traditionally described by phenomenological equations that relate the fluxes to the corresponding driving forces such as the Hagen – Poiseuille law, Fick's law, and Ohm's law.

For instance, a flux of mass caused by a hydrostatic pressure gradient is described by the *Hagen – Poiseuille law*:

$$J_v = -L_p \frac{\mathrm{d}\,p}{\mathrm{d}\,z}[\mathrm{m\,s^{-1}}] \tag{2.6}$$

A flux of individual components caused by a concentration gradient is described by *Fick's law*:

$$J_i = -D_i \frac{\mathrm{d}\,C}{\mathrm{d}\,z}\left[\mathrm{mol\,m^{-2}\,s^{-1}}\right] \tag{2.7}$$

A flux of electrical charges caused by an electrical potential gradient is described by *Ohm's law*:

$$J_e = -\kappa \frac{\mathrm{d}\,\varphi}{\mathrm{d}\,z}[\mathrm{A\,m^{-2}}] \tag{2.8}$$

where *C* is the concentration, *p* the pressure, φ the electrical potential, *D* the diffusion coefficient, L_p the hydrodynamic permeability, κ the electrical conductivity, and the subscripts v, *i*, and e refer to volume, individual components, and electrical charges.

Unfortunately, the simple linear relations expressed in Equations (2.6) to (2.8) are not suited to describe the mass transport in many of the technically relevant membrane processes. First, the conditions in the membrane are generally not ideal, and the concentration of individual components must be replaced by their activities. Furthermore, in many membrane processes mass transport is the result of a combination of driving forces; for example, in reverse osmosis and ultrafiltration the mass flux is caused by pressure and concentration gradients, and in electrodialysis the flux is due to an electrical potential and a concentration gradient. In these processes transport must be described by more complex relations based on Equation (2.3). Only in membrane processes such as microfiltration, where the mass transport is the result of only a single driving force (i.e., a hydrostatic pressure gradient), or in dialysis, where the driving force is a concentration gradient, can Equation (2.3) be replaced by a simpler linear relation between one driving force and the corresponding flux, such as the Hagen – Poiseuille law or Fick's law.

Furthermore, in membrane processes driving forces and fluxes may be interdependent, giving rise to new effects. For instance, a concentration or activity gradient across a membrane may not only result in diffusion of certain components through the membrane. Under certain conditions it can also cause the buildup of a hydrostatic pressure difference across the membrane. This phenomenon is referred to as osmosis and the generated pressure is referred to as osmotic pressure. Similarly, a gradient in hydrostatic pressure may not only lead to volume flux, but may also result in the buildup of a concentration difference across the membrane. This phenomenon is called reverse osmosis. An electrical potential gradient may not only result in an electric current but also in the transport of individual ions and buildup of a hydrostatic pressure. These phenomena are referred to as electrodialysis and electroosmosis.

In practice mass transport in membranes can be described by postulating certain membrane models, such as the pore model and the solution-diffusion model. In these models any kinetic coupling between individual fluxes is neglected. A more comprehensive treatment of the mass transport in multicomponent mixtures is based on the thermodynamics of irreversible processes. Here, the fluxes of individual components are described in a set of phenomenological equations which relate the fluxes of electrical charges, momentum, and individual components to the driving forces and which also take a coupling of different fluxes into account. Another approach to describe mass transport in membranes, suggested by Stefan – Maxwell, also describes the transport of the individual components in a set of phenomenological equations.

Phenomenological description of mass transport. A flux of individual components, heat, and electrical charges can be expressed in the following general equation [47]:

$$J_i = \sum_k L_{ik} X_k (i, k = 1, 2, 3, \ldots, n) \tag{2.9}$$

Here J_i refers to fluxes of individual components, heat and electric charges, X_k refers to the driving forces related to the fluxes, and L_{ik} is a phenomenological coefficient relating flux and driving force.

For multicomponent systems with fluxes of heat, electric charges, and neutral components Equation (2.9) can be written as a matrix. The diagonal coefficients relate the fluxes to the corresponding driving forces, and the cross-coefficients express the coupling of fluxes with indirectly conjugated driving forces [47].

Membrane processes are irreversible. Therefore, the entropy increases during the process. Based on the thermodynamics of irreversible processes it can be shown that the diagonal coefficients are always positive, while the cross-coefficients may be positive or negative and their number is reduced by the so-called Onsager relation [48].

To describe the transport in a multicomponent system such as an electrolyte solution with gradients in hydrostatic pressure, chemical potential, and electrical potential as driving forces, a very large number of phenomenological coefficients must be known which may be a function of temperature, pressure, or composition but which are by definition independent of the driving forces. This limits the practical use of Equation (2.9) substantially. However, under practical conditions many of the phenomenological coupling coefficients can be neglected and the rather complex set of equations can be reduced to more simple relations such as Fick's law or Ohm's law.

Another approach to describe mass transport in membrane processes is based on a relation developed by Maxwell and Stefan. This approach is based on the assumption that at a constant flux of a component *i* the driving forces acting on this component are equal to the sum of the friction forces between the component *i* and other components in the system [49]. If viscous flow (i.e., convection) is excluded the Stefan – Maxwell equation is given by [50]:

$$X_i = \sum_k \frac{f_{ik}}{C_i}\left(v_i - v_k\right) = \sum_k \frac{RT}{Đ_{ik} C_i}\left(v_i - v_k\right) \tag{2.10}$$

where *X* is the driving force, *C* the concentration, *v* the linear velocity, *f* the friction coefficient, Đ the Stefan – Maxwell diffusion coefficient, and subscripts *i* and *k* refer to individual components. The flux of an individual component is always proportional to its velocity relative to the velocity of another component which is used as a frame of reference. Thus, the number of independent fluxes in a given system is equal to the total number of components in the system minus the one that is used as reference. A system containing a membrane with *n* components, including the membrane, has *n*–1 independent fluxes.

The flux of component *i* relative to that of component *k* which serves as a frame of reference is given by:

$$J_i = C_i(v_i - v_k) \tag{2.11}$$

In membrane processes the fluxes through the membranes are of interest. Therefore, the membrane is used as frame of reference and its velocity is assumed to be zero.

Combination of Equations (2.9) to (2.11) provides the relation between the various terms of the phenomenological equation and the Stefan – Maxwell equation:

$$\sum_i L_{ik} = \sum_i \frac{C_i}{f_{ik}} = \sum_i C_i \frac{Đ_{ik}}{RT} \tag{2.12}$$

Equation (2.11), that is, the Stefan–Maxwell relation, provides the same complete description of transport processes through a membrane separating two homogeneous mixtures as does the phenomenological Equation (2.9) based on the thermodynamics of irreversible processes. The only further boundary condition relevant for a system which contains electrically charged components is the electroneutrality requirement and the conservation of electrical charges. For all phenomena observed in membrane systems, such as osmosis, electro-osmosis, diffusion of individual components, viscous flow of a bulk solution, electric current, or the buildup of an osmotic pressure, a streaming and a diffusion potential can be described by applying Equation (2.9) or (2.10). However, as mentioned before, the practical value of these equations is rather limited since they are only applicable close to equilibrium because of the assumed linear relationships between fluxes and driving forces and the large number of different coefficients that must be known when multicomponent systems with viscous flow, diffusion, and migration are to be treated. But even if the phenomenological treatment of mass transport in membrane processes is of little practical use, it indicates how complex the processes in multicomponent systems and heterogeneous membranes really are. It shows that through the coupling of fluxes a transport of components can be obtained without a directly related driving force. The magnitude of the transport of certain components obtained through coupling with other fluxes depends on the coupling coefficient. In many cases the coupling between fluxes can be neglected. In some cases, however, it can be significant. For instance, in electrodialysis the coupling of water with an ion flux can lead to significant water transport through a membrane. A more simplified approach to describe mass transport in electrolyte solution is provided by the so-called Nernst – Planck flux equation which can be derived from Equation (2.9) or (2.10) by introducing the electrochemical potential as driving force for mass transport and by neglecting all other kinetic coupling between individual components.

The electrochemical potential η is given by the chemical potential μ and the electrical potential φ:

$$\eta_i = \mu_i + z_i F \varphi = \mu_i^o + \overline{V}_i p + RT \ln a_i + z_i F \varphi \tag{2.13}$$

where *a* is the activity, *p* the hydrostatic pressure, $\overline{V}$ the partial molar volume, *z* the valence, *F* the Faraday constant, *R* the gas constant, *T* the absolute temperature, subscript *i* refers to a component, and superscript o to a standard state.

Introducing the activity coefficient and the ion concentration for the ion activity into Equation (2.13) and differentiation in transport direction *z*, that is, perpendicular to the membrane surface, leads to:

$$\frac{\mathrm{d}\,\eta_i}{\mathrm{d}\,z} = \overline{V}_i \frac{\mathrm{d}\,p}{\mathrm{d}\,z} + RT\frac{\mathrm{d}\,\ln\,(C_i\,\gamma_i)}{\mathrm{d}\,z} + z_i F \frac{\mathrm{d}\,\varphi}{\mathrm{d}\,z} \tag{2.14}$$

where *C* is the concentration, and γ the activity coefficient.

In electrodialysis and other ion-exchange membrane separation processes the pressure difference across the membrane is kept as low as possible to minimize viscous flow. Therefore, the term $\overline{V}_i \frac{\mathrm{d}\,p}{\mathrm{d}\,z}$ in Equation 2.14 can generally be neglected and the term $RT\frac{\mathrm{d}\,\ln(C_i\gamma_i)}{\mathrm{d}\,z}$ can be expressed by $\frac{RT}{C_i}\left(1 + C_i\frac{\mathrm{d}\,\ln\gamma_i}{\mathrm{d}\,C_i}\right)\frac{\mathrm{d}\,C_i}{\mathrm{d}\,z}$.

Thus:

$$\frac{\mathrm{d}\,\eta_i}{\mathrm{d}\,z} = \frac{RT}{C_i}\left(1 + C_i\frac{\mathrm{d}\,\ln\,\gamma_i}{\mathrm{d}\,C_i}\right)\frac{\mathrm{d}\,C_i}{\mathrm{d}\,z} + Fz_i\frac{\mathrm{d}\,\varphi}{\mathrm{d}\,z} \tag{2.15}$$

Introducing the gradient of the electrochemical potential of a component in the membrane expressed in Equation (2.15) as driving force X_i into Equations (2.10) and (2.11) gives the anion and cation fluxes of a completely dissociated salt:

$$J_i = -\text{Đ}_i\left[\left(1 + C_i\frac{d\,\ln\,\gamma_i}{dC_i}\right)\frac{dC_i}{dz} + \frac{z_i C_i F}{RT}\frac{d\varphi}{dz}\right] + v_k C_i \tag{2.16}$$

If the solution is assumed to be ideal, that is, the activity of a component is identical to its concentration, the Stefan – Maxwell diffusion coefficient can be replaced by Fick's diffusion coefficient, and Equation (2.16) is simplified to:

$$J_i = -D_i\frac{\mathrm{d}\,C_i}{\mathrm{d}\,z} - D_i\frac{z_i C_i F}{RT}\frac{\mathrm{d}\,\varphi}{\mathrm{d}\,z} + v_k C_i \tag{2.17}$$

Equation (2.17) represents the extended Nernst – Planck flux equation where D_i is Fick's diffusion coefficient of component *i* relative to the water in the membrane.The first term $D_i\frac{\mathrm{d}\,C_i}{\mathrm{d}\,z}$ in Equation (2.17) represents diffusion, the second term $D_i\frac{z_i C_i F}{RT}\frac{\mathrm{d}\,\varphi}{\mathrm{d}\,z}$ migration, and the third term $v_k C_i$ convection.

Fick's diffusion coefficient is related to the Stefan – Maxwell diffusion coefficient and the phenomenological coefficient by:

$$D_i = L_i\frac{RT}{C_i}\left(1 + \frac{\mathrm{d}\,\ln\,\gamma_i}{\mathrm{d}\,\ln\,C_i}\right) \tag{2.18}$$

and

$$D_i = \text{Đ}_i\left(1 + \frac{\mathrm{d}\,\ln\,\gamma_i}{\mathrm{d}\,\ln\,C_i}\right) \tag{2.19}$$

The Nernst – Planck equation becomes identical with the phenomenological equation of the thermodynamics of irreversible processes and the Stefan – Maxwell equation if kinetic coupling between individual ions is neglected and if the activity coefficient is assumed to be unity. The Nernst – Planck flux equation is a very convenient approach to describe the transport of ions in ion-exchange membranes. It must, however, be realized that a series of assumptions has been made which in practical ion-exchange membrane separation processes are not always applicable.

2.5. Membrane Separation Capability

In most technically relevant applications the capability of a membrane to separate different components from each other, that is, the membrane permselectivity, is the most important membrane property. This separation capability can be expressed by the selectivity or by the rejection [51].

The membrane selectivity is given by:

$$S^{\mathrm{P}}_{\mathrm{A,B}} = \frac{P_{\mathrm{A}}}{P_{\mathrm{B}}} \tag{2.20}$$

and the membrane rejection by:

$$R_{\mathrm{A}} = \left(1 - \frac{C'_{\mathrm{A}}}{C''_{\mathrm{A}}}\right) \tag{2.21}$$

where $S^{\mathrm{P}}_{\mathrm{A,B}}$ is the permselectivity of a membrane for the components A and B, and P_A and P_B are their permeability; R_A is the rejection of component A by the membrane; C_A' and C_A'' are the concentrations of component A in the two phases separated by the membrane, for instance, a feed solution and a filtrate when a filtration process is considered.

2.6. Chemical and Electrochemical Equilibrium in Membrane Processes

Equilibrium between two systems such as a membrane and an adjacent solution or two solutions separated by a membrane is obtained when the systems are in the same state, that is, when the Gibbs free energies in both systems are identical. The Gibbs free energy of a system is a function of various state variables such as pressure, electrical potential, and the activity of individual components. Consider a system separated by a membrane which is impermeable to some components and permeable to others. These two systems may well be in equilibrium even if they have differences in pressures, electrical potentials, or the activities of individual components as long as these differences compensate each other and the sum of the state variables (i.e., the Gibbs free energy) in both systems is identical. Examples for two such equilibria are the osmotic equilibrium, in which pressure and activity differences compensate each other, and the Donnan equilibrium which is attained when an electrical potential difference is compensated by an activity difference. For membrane processes the osmotic and Donnan equilibrium are both of importance and will be discussed in more detail.

2.6.1. *Osmotic Equilibrium, Osmotic Pressure, Osmosis, and Reverse Osmosis*

If two aqueous salt solutions of different concentrations are separated by a membrane which is permeable for the solvent (e.g., water) but impermeable for the solute (e.g., salt), transport of water from the more dilute solution to the more concentrated solution is observed. This phenomenon (Fig. 4) is referred to as osmosis.

Figure 4. Schematic illustrating the osmotic phenomenon. It shows two phases (′ and ″) separated by a semipermeable membrane. The phases consist of a solvent and a solute, indicated by the subscripts l and s. *C* and μ are concentration and chemical potential, *p* is hydrostatic and π osmotic pressure, and *J* the membrane flux

The figure shows a schematic diagram of a membrane separating two solutions consisting of a solvent and a solute, a salt. The two solutions are indicated by ′ and ″. The membrane is assumed to be permeable to the solvent, but impermeable to the solute. Depending on the concentrations and hydrostatic pressures in the two phases separated by the membrane four different situations can be distinguished:

1. The hydrostatic pressures in the two phases separated by the membrane are equal but the solute concentration in solution′ is higher than that in solution″. In this case the osmotic pressure in solution′ is higher than that in solution″ and flow of solvent occurs from the more dilute solution into the more concentrated solution . This situation is referred to as *osmosis*.
2. The two phases separated by the membrane have different hydrostatic pressures, but the difference in hydrostatic pressure is equal to the difference in the osmotic pressures between the two solutions acting in opposite direction. This situation is referred to as *osmotic equilibrium* and there will be no flow of solvent through the membrane although the concentrations in the two solutions are different.
3. The two phases separated by the membrane have different hydrostatic pressures, but the difference in hydrostatic pressure across the membrane is larger than the osmotic pressure and acts in the opposite direction. Thus, solvent will flow through the membrane from solution′ with the higher solute concentration into solution″ with the lower solute concentration. This phenomenon is referred to as *reverse osmosis*.

The flux of solvent between two homogeneous solutions of different concentrations separated by a semipermeable membrane which is only permeable for the solvent to the more concentrated solution as a function of applied hydrostatic pressure is illustrated in Figure 5. Here, the solvent flux between two solutions of different concentrations through a strictly semipermeable membrane is shown as a function of the hydrostatic pressure applied to the more concentrated solution.

Figure 5. Solvent flux between two solutions of different concentrations through a strictly semipermeable membrane as function of hydrostatic pressure applied to the more concentrated solution

As long as the applied hydrostatic pressure is lower than the osmotic pressure difference between the two solutions, solvent will flow from the more dilute solution into the more concentrated solution by osmosis. When the hydrostatic pressure exceeds the osmotic pressure difference the flow is reversed and solvent will flow from the more concentrated solution to the dilute solution. This process is referred to as reverse osmosis.

The osmotic pressure π of a solution is proportional to the solute concentration C_s, but it can be calculated from the chemical potential of the solvent in a solution and is given by:

$$\pi = \frac{RT}{V_l} \ln a_l \tag{2.22}$$

For dilute solutions the osmotic pressure can be expressed to a first approximation by the concentration of the individual components in the solution [46]:

$$\pi = RT \sum_i g_i C_i \tag{2.23}$$

If the solute is a salt, as is the case in many practical applications, the concentration of the individual ions must be considered when determining the osmotic pressure, that is, the degree of dissociation and the stoichiometric coefficients of

the salt must be considered for determining the osmotic pressure.

The osmotic pressure of an aqueous solution with salts is given by:

$$\pi = RT\sum_i g_i(v_{ic} + v_{ia})C_{is} \tag{2.24}$$

where *g* is the osmotic coefficient and the subscripts s, c, and a respectively refer to a stoichiometric coefficient, cation, and anion.

2.6.2. *Donnan Equilibrium and Donnan Potential*

In discussing the osmotic pressure it was assumed that two solutions separated by a membrane are in chemical equilibrium. If the solution contains charged components (i.e., ions) and the membrane is permeable for at least one ionic component, the membrane will be in equilibrium with the adjacent solution if the electrochemical potential of all ions in the membrane and the solution are equal. Thus, for each ion in equilibrium is:

$$\eta_i^m = \eta_i^s = \mu_i^m + z_i F\varphi^m = \mu_i^s + z_i F\varphi^s \tag{2.25}$$

where μ_i and η_i are the chemical and the electrochemical potential, respectively of component *i*, φ is the electrical potential, *F* the Faraday constant, and superscripts m and s refer to the membrane and to the solution, respectively.

Thus, the electrochemical potential of an ion is composed of two additive terms: the chemical potential, and the electrical potential multiplied by the Faraday constant and the valence of the ion. Introducing the chemical potential μ_i as defined in Equation (2.13) into Equation (2.25) and rearranging gives the electrical potential difference between the membrane and the adjacent solution as:

$$\varphi^m - \varphi^s = \frac{1}{z_i F}\left[RT \ln \frac{a_i^s}{a_i^m} + \overline{V}_i \quad (p^s - p^m)\right] = \varphi_{Don} \tag{2.26}$$

where φ is the electrical potential, *a* the ion activity, $\overline{V}$ the partial molar volume, *z* the valence, *F* the Faraday constant, *p* the pressure, *T* the absolute temperature, *R* the gas constant, subscript *i* refers to individual components, and superscripts m and s refer to the membrane and the electrolyte solution, respectively. The potential difference between the membrane and the solution is referred to as Donnan potential φ_{Don}. [11].

The Donnan potential between an electrolyte solution and an ion-exchange membrane cannot be measured directly. It can, however, be calculated from the ion activities in the solution and the membrane, and by the pressure difference between the membrane phase and the adjacent solution, p^m–p^s, which is referred to as swelling pressure and is identical to the osmotic pressure difference between the solution and the membrane.

Introducing the osmotic pressure into Equation (2.26) gives the Donnan potential as a function of the ion and the water activities in the membrane and the solution:

$$\varphi_{Don} = \frac{1}{z_i F}\left[RT \ln \frac{a_i^s}{a_i^m} - \overline{V}_i \Delta\pi\right] \tag{2.27}$$

The numerical value of the Donnan potential φ_{Don} can be calculated either from the cation or anion activities. For a single salt it is:

$$\varphi_{Don} = \frac{1}{z_c F}\left[RT \ln \frac{a_c^s}{a_c^m} - \overline{V}_c \Delta\pi\right] = \frac{1}{z_a F}\left[RT \ln \frac{a_a^s}{a_a^m} - \overline{V}_a \Delta\pi\right] \tag{2.28}$$

Equation (2.28) gives a general relation for the cation and anion distribution at the interface between a solution and an ion-exchange membrane.

Note that the value of the Donnan potential is negative for an cation-exchange membrane and positive for an anion-exchange membrane in equilibrium with a dilute electrolyte solution.

The Donnan equilibrium describes the electrochemical equilibrium of an ion in an ion-exchange membrane and an adjacent solution and can be calculated for a single electrolyte by rearranging Equation (2.27):

$$\left(\frac{a_a^s}{a_a^m}\right)^{\frac{1}{z_a}}\left(\frac{a_c^m}{a_c^s}\right)^{\frac{1}{z_c}} = e^{\frac{\Delta\pi \overline{V}_s}{RT z_c \nu_c}} \tag{2.29}$$

where *z* is the valence, ν the stoichiometric coefficient of the electrolyte, *F* the Faraday constant, *R* the gas constant, *T* the absolute temperature, $\overline{V}$ the partial molar volume, and *a* the activity; the subscripts a and c refer to anion and cation, and the superscripts s and m to the solution and the membrane, respectively.

The Donnan equilibrium is an important relation in electro-membrane processes since it determines the distribution of co- and counterions between the membrane and the adjacent solution.

3. Principles of Membrane Separation Processes

Membrane separation processes can differ greatly with regard to membranes, driving forces, areas of application, and industrial or economic relevance. Table 1 summarizes industrially important membrane separation processes. The driving force in these processes can be a hydrostatic pressure gradient as in micro- and ultrafiltration, reverse osmosis, or gas separation; a concentration gradient as in dialysis; or an electrical potential gradient as in electrodialysis. In some membrane separation processes, for example, pervaporation and membrane distillation, partial pressure differences of individual components can be applied as driving force [51].

Table 1. Technically relevant membrane separation processes, their operating principles, and their applications.

Separation Process	Membrane type used	Applied driving force	Mode of separation	Applications
Microfiltration	symmetric porous membrane, pore radius 0.1–10 mm	hydrostatic pressure, 0.05 – 0.2 MPa	filtration (size exclusion)	water purification, sterilization
Ultrafiltration	asymmetric porous membranes, pore radius 2 – 10 nm	hydrostatic pressure, 0.1 – 0.5 MPa	filtration (size exclusion)	separation of molecular mixtures
Diafiltration	asymmetric porous structure,pore radius 2 – 10 nm	hydrostatic pressure, 0.1 – 0.5 MPa	filtration and dialysis (size exclusion)	purification of molecular mixtures, artificial kidney
Reverse osmosis	asymmetric skin-type solution-diffusion membrane	hydrostatic pressure, 1 – 10 MPa	solution and diffusion	sea- and brackish water desalination
Gas and vapor separation	homogeneous or porous membrane	hydrostatic and vapor pressure	diffusion, Knudsen diffusion	separation of gases, vapors, and isotopes
Pervaporation	homogeneous asymmetric membrane	vapor pressure	solution and diffusion	separation of azeotropic mixtures
Dialysis	symmetric porous membrane	concentration gradient	diffusion	artificial kidney
Electrodialysis	symmetric ion-exchange membrane	electrical potential	Donnan exclusion	water desalination
Donnan dialysis	symmetric ion-exchange membrane	concentration of ions	Donnan exclusion	water softening
Electrodialytic water splitting	bipolar membrane	electrical potential	Donnan exclusion	acid and base production
Membrane distillation	symmetric porous hydrophobic membrane	vapor pressure	diffusion	liquid – solid separation
Membrane contactors	symmetric porous or liquid membrane	chemical potential	diffusion and solution	solvent extraction

Membrane separation processes can conveniently be classified according to the driving forces applied to achieve the transport of certain components through the membrane into pressure-driven, concentration-driven, and electrical-potential-driven processes. Typical pressure-driven membrane processes are microfiltration, ultrafiltration, and reverse osmosis. In all three processes a feed solution is separated into a filtrate that is depleted of particles or molecules and a retentate in which these components are concentrated.

The term *microfiltration* is used when particles with a diameter of 0.1 – 10 µm are separated from a solvent or other low-molecular components. The separation mechanism is based on a sieving effect, and particles are separated according to their dimensions. The membranes used for microfiltration have pores of 0.1 – 10 µm in diameter. The hydrostatic pressure differences used are in the range of 0.05 – 0.2 MPa.

In *ultrafiltration* the components to be retained by the membrane are macromolecules or submicrometer particles. Generally, the osmotic pressure of the feed solution is negligibly small and hydrostatic pressures of 0.1 – 5 MPa are used. Ultrafiltration membranes are mostly asymmetrically structured, with pores in the skin layer having diameters of 2 – 10 nm.

Diafiltration is in principle identical to ultrafiltration. It is used to rinse out low molecular weight components such as salts from a solution with macromolecular components.

In *reverse osmosis* particles, macromolecules, and low molecular mass compounds such as salts and sugars are separated from a solvent, usually water. Feed solutions, therefore, often have a significant osmotic pressure, which must be overcome by the applied hydrostatic pressure. The osmotic pressure of a solution containing low molecular mass solutes can be quite high even at low solute concentrations. Since the membrane flux is a function of the effective pressure, which is given by the hydrostatic pressure difference between feed and filtrate solutions minus the difference in osmotic pressure between these solutions, and the osmotic pressure is relatively high, hydrostatic pressures on the order of 1 – 10 MPa are used in practical applications.

In *dialysis* certain solutes are transferred from a the feed solution to a receiving solution, which is also referred to as stripping solution or dialysate, through a membrane due to a concentration gradient across the membrane. The separation of various compounds is the result of differences in their diffusivity in the membrane matrix.

In *electrodialysis* an electrical potential driving force and anion- and cation-exchange membranes installed in alternating series between electrodes are used to separate charged components such as ions from a solution. The separation is the result of the permselectivity of the ion-exchange membranes, which are permeable only to counterions, that is, cation-exchange membranes are permeable to cations and anion-exchange membrane are permeable to anions.

Electrodialytic water dissociation is a process similar to electrodialysis in which monopolar ion-exchange membranes are used in combination with bipolar membranes which split water into H^+ and OH^- ions to produce acids and bases from the corresponding salt.

In *gas and vapor separation* two different processes and membranes are used. One is similar to reverse osmosis using asymmetric solution-diffusion membranes and a hydrostatic pressure as driving force. The membrane selectivity is determined by the solubility and diffusion of the components in the membrane matrix. In the second process, porous membranes are used through which gases permeate at elevated temperature under a hydrostatic pressure as driving force by Knudsen diffusion. The selectivity is very low and a large number of stages are required to obtain significant separation of the permeating components. Knudsen diffusion separation is used mainly for the separation of radioactive isotopes.

In *pervaporation* volatile organic compounds are removed from a liquid feed solution through a solution-diffusion membrane into the gas phase as a result of a difference in their partial vapor pressure. Both hydrostatic pressure and temperature differences are used as driving force for the transport of the different components through the membrane.

Membrane distillation is similar to conventional distillation. The main difference is that the feed and the product are separated by a porous membrane.

Membrane contactors are used in solvent extraction. Here, the membrane acts as barrier between the feed and the stripping solution.

3.1. Principle of Microfiltration

The principle of microfiltration is depicted in Figure 6. The membrane separating a feed solution from a permeate or filtrate has a symmetric porous structure with an average pore size between 0.1 and 10 µm. The driving force for the mass transport across the membrane is a pressure gradient. Only large particles with diameters in excess of about 0.1 µm are separated by the membrane. The diffusion of particles and the osmotic pressure difference between the feed and filtrate solution are negligibly low and the mass flux through a microfiltration membrane is given to a first approximation by:

$$J_v = \sum_i J_i \overline{V}_i \cong L_v \frac{\Delta p}{\Delta z} \tag{3.1}$$

where J_v is the volume flux across the membrane, the subscripts *v* and *i* refer to volume and components in the solution, $\overline{V}$ is the partial molar volume, *p* the pressure, and L_v a phenomenological coefficient referring to hydrodynamic permeability of the membrane, Δp the pressure difference between the feed and filtrate solution, and Δz the thickness of the membrane.

Figure 6. Schematic illustrating the principle of microfiltration

The mass transport in microfiltration membranes takes place by viscous flow through the pores. The solid membrane matrix can be considered as completely impermeable. Therefore, the hydrodynamic permeability can be expressed in terms of the membrane pore size and the porosity and the solution viscosity according to the Hagen – Poiseuille law, which is given by:

$$J_v = \frac{\varepsilon r^2}{8\eta\tau} \frac{\Delta p}{\Delta z} \tag{3.2}$$

where J_v is the flux, ε the membrane porosity, *r* the pore radius, η the viscosity, τ the tortuosity factor, Δp the pressure difference across the membrane, and Δz the membrane thickness.

The tortuosity factor is defined as the ratio of the actual pore length to the thickness of the membrane taking into account that the pore length in general is somewhat longer than the cross section of the membrane. Thus, τ is always greater than 1, and the porosity ε is always less than 1.

The flux through a microfiltration membrane, which is often referred to as filtration rate, is adequately described by Equation (3.2). Another parameter which is of interest for the practical application of microfiltration is the separation characteristic of a membrane. This is generally expressed by the retention or rejection of a particle of a certain size, which is given by:

$$R_i = \left(1 - \frac{C_i^p}{C_i^f}\right) \tag{3.3}$$

where *R* is the rejection coefficient, *C* is the concentration, subscript *i* refers to a given component in the feed and the permeate, and superscripts f and p refer to the feed and permeate or filtrate solutions. *R* is always less than or equal to 1 and a function of the particle and the pore size and pore size distribution.

3.2. Principle of Ultrafiltration

In ultrafiltration the driving force again is a pressure gradient and the mass transport is also dominated by the convective flux through pores. The principle of the process is depicted in Figure 7.

Figure 7. Schematic illustrating the principle of ultrafiltration

As in microfiltration a porous membrane and a hydrostatic pressure difference are used to separate certain components from a feed solution. However, the structure of an ultrafiltration membrane is asymmetric, with the smallest pores on the surface facing the feed solution, and its pores are significantly smaller than those of a microfiltration membrane. Their diameters at the feed side surface of the membrane are between 2 and 10 nm and the components retained by an ultrafiltration membrane have a molecular weight between 5000 and several million Dalton. Since ultrafiltration membranes also retain some relatively low molecular weight solutes, osmotic pressure differences between the feed and the filtrate can be significant and diffusive fluxes of the solutes across the membrane are no longer negligibly low. Therefore, the flux of individual components in ultrafiltration can be expressed as a function of a hydrostatic pressure and a difference in the chemical potential of the different components between the feed and filtrate solutions. The volume flux (i.e., the filtration rate) is given by the sum of the fluxes of the individual components:

$$J_v = \sum_i J_i \overline{V}_i = \sum_i \overline{V}_i L_i \frac{d\mu_i}{dz} + L_v \frac{dp}{dz} = \sum_i \overline{V}_i L_i \frac{d}{dz}(\overline{V}_i p + RT \ln a_i) + L_v \frac{dp}{dz} \tag{3.4}$$

where *J* is the flux, *L* a phenomenological coefficient referring to interactions of the permeating components with the membrane matrix, $\overline{V}_i$ the partial molar volume, μ the chemical potential, *p* the hydrostatic pressure, *z* a directional coordinate, *a* the activity, and the subscripts v and *i* refer to volume flow and individual components. The first term in Equation (3.4) describes the diffusive fluxes of all components in the pores of the membrane, and the second term the volume flow.

In ultrafiltration the total volume flux in a dilute solution can be expressed to a first approximation by the flux of the solvent, that is, $J_v \approx J_w$, and the activity of the solvent in the solution a_w can be expressed by an osmotic pressure. Assuming a linear relation for the pressure and activity gradients across the membrane, integration of Equation (3.4) gives the flux through an ultrafiltration membrane as a function of pressure difference between feed and permeate solution, the hydrodynamic permeability for the viscous flow, the osmotic pressure difference between feed and permeate solution, and the phenomenological coefficient determining the diffusive flow of water through the membrane pores:

$$J_v \cong J_w = \overline{V}_w^2 L_w \frac{\Delta p - \Delta \pi}{\Delta z} + L_v \frac{\Delta p}{\Delta z} \tag{3.5}$$

where J_v and J_w are total volume and solvent fluxes, respectively, Δp and $\Delta \pi$ are the hydrostatic and the osmotic pressure gradients across the membrane, L_v is the hydrodynamic permeability and L_w is the diffusive permeability of the solvent, and Δz is the thickness of the selective barrier of the membrane.

In most practical applications of ultrafiltration the first term of Equation (3.5) can be neglected since $L_w \ll L_v$. The osmotic water transport will effect the membrane volume flux only when the difference in osmotic pressure between the feed and permeate solution is significantly higher than the hydrostatic pressure difference. This is only the case for ultrafiltration of solutions containing a high concentration of retained components of relatively low molecular weight. Since generally only macromolecular components are retained the volume flux (i.e., the filtration rate in ultrafiltration) can be described to a first approximation by:

$$J_v = L_v \frac{\Delta p}{\Delta z} \tag{3.6}$$

For the transport of solutes through an ultrafiltration membrane the diffusive flux can generally not be neglected, and the flux of the solute through the membrane can be expressed as the sum of a diffusive flux due to a chemical potential driving force and a convective flux due to the concentration in the pore solution:

$$J_i = \overline{V}_i L_i \frac{d}{dz}(\overline{V}_i p + RT \ln a_i) + L_v {}^{m}C_i \frac{dp}{dz} \tag{3.7}$$

where ${}^{m}C_i$ is the concentration of the solute in the pore solution.

It can be shown that for hydrostatic pressure differences usually applied in ultrafiltration, $\overline{V}_i p << RT \ln a_i$. If it is assumed that the activity coefficient of the solutes in the membrane is 1, the phenomenological coefficient can be expressed by the Fick's

diffusion coefficient according to Equation (2.19). Introducing these approximations into Equation (3.7) leads to:

$$J_i = J_v {}^{m}C_i - {}^{m}D_i \frac{d\,{}^{m}C_i}{d\,z} \tag{3.8}$$

Integration of Equation (3.8) over the membrane thickness gives:

$$J_i = J_v \frac{{}^{m}C_i^f \exp\frac{J_v \tau \Delta z}{{}^{m}D_i} - {}^{m}C_i^p}{\exp\frac{J_v \tau \Delta z}{{}^{m}D_i} - 1} \tag{3.9}$$

where *J* is the flux, *C* the concentration, *D* the diffusion coefficient, τ the tortuosity factor, and Δz the thickness of the membrane; subscripts *i* and v refer to solute and the volume; and superscripts m, f,and p refer to the membrane, the solution in the membrane at the feed side, and the solution in the membrane at the permeate side.

Equation (3.9) shows that the flux of a component *i* which is partly retained by the membrane in ultrafiltration consists of two terms. The first term represents the viscous flow and is a linear function of the hydrostatic pressure. The second term represents the diffusion in the pore liquid and is an exponential function of the hydrostatic pressure.

In ultrafiltration two limiting cases exist for the transport mechanism. In the first case it is assumed that the hydrostatic pressure and thus the viscous flow is zero, so that the transport of a solute is determined by diffusion only:

$$\lim_{J_v \to 0} J_i = -{}^{m}D_i \frac{{}^{m}C_i^p - {}^{m}C_i^f}{\tau \Delta z} \tag{3.10}$$

The second limiting case is obtained when the pressure and thus the viscous flow is infinitely high. Then the transport of the solute is determined by its concentration in the membrane:

$$\lim_{J_v \to \infty} J_i = J_v {}^{m}C_i^p \tag{3.11}$$

Since the flux of the solute in ultrafiltration is a function of the viscous flux the retention of an ultrafiltration membrane is obviously a function of the applied hydrostatic pressure. It can be described by combining Equations (3.3) and (3.9) and by introducing partition coefficients to relate the concentrations of the solute in the feed and the permeate to that in the membrane:

$$R_i = 1 - \frac{k^f \exp\frac{J_v \tau \Delta z}{{}^{m}D_i}}{k^p - 1 + \exp\frac{J_v \tau \Delta z}{{}^{m}D_i}} \tag{3.12}$$

where

$$k^f = \frac{C_i^f}{{}^{m}C_i^f} \text{ and } k^p = \frac{C_i^p}{{}^{m}C_i^p} \tag{3.13}$$

where k^f and k^p are the partition coefficients which relate the concentrations in the feed and the permeate to that in the membrane.

The effect of the hydrostatic pressure on retention in ultrafiltration becomes more clear when two extreme cases are considered, that is, a very large and a very small hydrostatic pressure difference between feed and permeate solutions. At large pressure differences the viscous flux is high and the retention approaches a maximum value which is determined by the distribution coefficient of the solute between the membrane and the solution.

$$\lim_{J_v \to \infty} R_i = 1 - k^f \tag{3.14}$$

At very low hydrostatic pressure the retention goes to zero.

$$\lim_{J_v \to \infty} R = 0 \tag{3.15}$$

3.3. Principle of Reverse Osmosis

In reverse osmosis the driving force is also a hydrostatic pressure difference. The principle of the process is illustrated in Figure 8, which shows a solution containing a low molecular weight component separated by a membrane from the solvent and a hydrostatic pressure difference applied across the membrane resulting in a flux of solvent from the solution into the pure solvent.

Figure 8. Schematic illustrating the principle of reverse osmosis

The membrane used in reverse osmosis has an asymmetric structure with a dense barrier layer at the side facing the feed solution. It is assumed that in this layer the individual components are transported by diffusion and that viscous flow through

pores or pinholes can be neglected. For describing the transport in reverse osmosis membranes two approaches are described in the literature [52]. One is the so-called solution-diffusion model, which neglects kinetic coupling of different fluxes [23]. The second is based on the phenomenological equation of the thermodynamics of irreversible processes [47]. This model does consider kinetic coupling between different fluxes. Both models describe the transport in reverse osmosis membranes quite accurately, and this indicates that kinetic coupling is not of great importance in reverse osmosis.

3.3.1. *Mass Transport in Reverse Osmosis Described by Phenomenological Equations*

In a reverse osmosis system which consists of a membrane and a two-component feed solution, i.e. a solvent and a solute, two independent fluxes will be obtained when the membrane is used as frame of reference. These fluxes can be described by:

$$J_i = \sum_k L_{ik} X_k \quad (i,\ k = 1, 2, 3,\ \ldots,\ n) \tag{3.16}$$

where J is the flux of the different components, L is the phenomenological coefficient, X the driving force, and subscripts i and k refer to different components.

Assuming a system without viscous flow composed of a solute, a solvent, and a membrane as frame of reference there are two independent fluxes:

$$J_w = L_w \, d\mu_w + L_{ws} \, d\mu_s \tag{3.17}$$

and

$$J_s = L_{sw} \, d\mu_w + L_s \, d\mu_s \tag{3.18}$$

where J is the flux, μ the chemical potential, L the phenomenological coefficient, subscripts w and s refer to the solvent, which is assumed to be water, and the solute, which is assumed to be salt, and subscripts ws and sw to the coupling between the fluxes of water and salt and salt and water.

The coupling coefficients L_{sw} and L_{ws} are identical according to the Onsager relation [48]. They are very difficult to measure in an independent experiment. However, the coupling coefficient can be converted to more easily measurable constants when the phenomenological equations are slightly modified.

Usually in reverse osmosis the total volume flux is measured. It is therefore possible to consider a volume flux J_v and a diffusion related flux J_D which are given by [20]:

$$J_v = J_w \overline{V}_w + J_s \overline{V}_s \tag{3.19}$$

$$J_D = \frac{J_s}{C_s} - \overline{V}_w J_w \tag{3.20}$$

The dissipation function for the above described set of equations is:

$$\Psi = J_w \, d\mu_w + J_s \, d\mu_s = J_w \, d(\overline{V}_w p + RT \ln a_w) + J_s \, d(\overline{V}_s p + RT \ln a_s) \tag{3.21}$$

where Ψ is the dissipation function, J the flux, C, a, μ, and $\overline{V}$ are the concentration, the activity, the chemical potential, and the partial molar volume in the membrane, p is the hydrostatic pressure, and subscripts v, w, s, and D refer to volume, solvent, solute, and diffusion.

Assuming a linear relation for the chemical potential gradients, introducing the osmotic pressure for the activities of water and solute as described in Equations (2.22) and (2.23), and inserting Equations (3.19) and (3.20) into Equation (3.21) leads to a new set of phenomenological equations:

$$\Psi = (J_w \overline{V}_w + J_s \overline{V}_s) \Delta p + \left(\frac{J_s}{C_s} - J_w \overline{V}_w \right) \Delta \pi = J_v \Delta p + J_D \Delta \pi \tag{3.22}$$

The first term in Equation (3.22) describes the total volume flux J_v as function of the applied pressure and the second term describes the diffusion flux of the salt J_D.

The new set of phenomenological equations is:

$$J_v = L_p \Delta p + L_{pD} \Delta \pi \tag{3.23}$$

$$J_D = L_{Dp} \Delta p + L_D \Delta \pi \tag{3.24}$$

By applying different experimental conditions and Equations (3.23) and (3.24) the phenomenological coefficients can be determined from experimental measurements.

Assuming no pressure difference is applied ($\Delta p = 0$), then the diffusive flux is given by:

$$(J_D)_{\Delta p = 0} = L_D \Delta \pi \tag{3.25}$$

and the volume flux is given by:

$$(J_v)_{\Delta p=0} = L_{pD}\,\Delta\pi \tag{3.26}$$

Assuming that there is no osmotic pressure difference ($\Delta\pi$ = 0), then the diffusive flux is given by:

$$(J_D)_{\Delta\pi=0} = L_{Dp}\,\Delta p \tag{3.27}$$

and the volume flux by:

$$(J_v)_{\Delta\pi=0} = L_p\,\Delta p \tag{3.28}$$

The hydrostatic pressure difference at zero volume flux, that is, the osmotic equilibrium, is given by:

$$(\Delta p)_{J_v=0} = -\frac{L_{pD}}{L_p}\Delta\pi = \sigma\,\Delta\pi \tag{3.29}$$

where σ is the so-called Staverman reflection coefficient [53], which is a measure for the permselectivity of a membrane.

Equation (3.29) shows that in osmotic equilibrium the hydrostatic pressure difference between two solutions separated by a membrane is equal to the osmotic pressure difference if $L_p = L_{pD}$ and therefore σ = 1. This is only the case for a strictly semipermeable membrane. Usually, the Staverman reflection coefficient has values between 0 and 1.

If the volume flux is 0 the ratio of salt flux to osmotic pressure difference is given by:

$$\left(\frac{J_s}{\Delta\pi}\right)_{J_v=0} = \frac{C_s L_p L_D - L_{pD}^2}{L_p} = \omega \tag{3.30}$$

where ω is the permeability of the salt.

Combining Equations (3.20), (3.23), (3.24), (3.29), and (3.30) leads to:

$$J_v = L_p(\Delta p - \sigma\,\Delta\pi) \tag{3.31}$$

$$J_s = C_s(1-\sigma)J_v + \omega\,\Delta\pi \tag{3.32}$$

Based on the phenomenological equations the mass transport in reverse osmosis of a solution of a single salt solution can be described by three coefficients:the hydrodynamic permeability of the membrane L_p, the salt permeability, ω and the reflection coefficient σ. All three coefficients can be experimentally determined.

3.3.2. *Description of Mass Transport in Reverse Osmosis by the Solution-Diffusion Model*

In the solution-diffusion model the flux of different components through a membrane is assumed to be caused by diffusion and can be described by the product of its concentration and mobility in the membrane and the chemical potential gradient of the component in the membrane. Furthermore, it is assumed that there is no coupling between fluxes, that the volume flux is approximately identical to the flux of the solvent, and that the solute flux due to the pressure gradient is negligibly small.

Thus, the flux of a component in the membrane is given by:

$$J_i = {}^{m}C_i m_i = L_i\,\mathrm{d}\,\mu_i = L_i(\overline{V}_i\,\mathrm{d}\,p + RT\,\mathrm{d}\ln a_i) \tag{3.33}$$

where J is the flux, ${}^{m}C$ the concentration, m the mobility, L a phenomenological coefficient composed of a concentration and a mobility term, μ the chemical potential, p the hydrostatic pressure, a the activity, $\overline{V}$ the partial molar volume, and subscript i refers to a component.

For i = w it is assumed that $J_v \cong J_w$ and thus $C_w\overline{V}_w = 1$. For i = s it is assumed that d $\mu_s \cong RT\mathrm{d}\ln a_s$ and $\pi \cong \frac{RT\ln a_w}{\overline{V}_w}$. Here the subscripts v, w, and s refer to volume, solvent, and solute.

Integrating over the cross section of the membrane and expressing the activity of the solvent by the osmotic pressure and that of the solute by its concentration gives the volume flux as

$$J_v = L_w\overline{V}_w(\Delta p - \Delta\pi) \tag{3.34}$$

and the solute flux as:

$$J_s = L_s\frac{RT}{C_s}\Delta^{m}C_s \tag{3.35}$$

The concentration of the different components in the membrane is proportional to the concentration in the outside solutions and given by:

$${}^{m}C_i = k_i C_i \tag{3.36}$$

where k_i is the partition coefficient of component i between the membrane and the adjacent solution, and C_i and ${}^{m}C_i$ are the concentrations in the outside solution and in the membrane.

Introducing Equation (3.36) and Fick's diffusion coefficient according to Equation (2.18) into Equations (3.35) and (3.34) gives the volume flux (i.e. the filtration rate) and the flux of the solute as function of the applied hydrostatic pressure, the osmotic pressure, the diffusion coefficient of the components in the membrane, their concentration in the feed and permeate solution, and their partition coefficient between the membrane and the solutions:

$$J_v = \frac{k_w D_w C_w \bar{V}_w}{RT}(\Delta p - \Delta \pi) = \frac{k_w D_w}{RT}(\Delta p - \Delta \pi) \tag{3.37}$$

and

$$J_s = k_s D_s \Delta C_s \tag{3.38}$$

where J_v is the volume flux, J_s the solute flux, D the diffusion coefficient, k the partition coefficient of the components between the membrane and the adjacent solutions, C the concentration, p the hydrostatic pressure and π the osmotic pressure of the solutions, subscripts s and w refer to solute and water, respectively, and the superscript m refers to the membrane. Furthermore it is assumed that $V_w C_w \cong 1$.

In Equations (3.37) and (3.38) all kinetic coupling between fluxes is neglected and activity coefficients in the membrane are assumed to be 1. Nevertheless, Equations (3.37) and (3.38) describe the mass transport in reverse osmosis for a membrane with a high solute rejection capability quite well, as a comparison with Equations (3.31) and (3.32) shows, since the reflection coefficient is very close to 1 for a membrane with a high salt rejection.

Besides the volume flux (filtration rate) and the solute flux, the rejection of the membrane is of interest. The rejection is given by Equation (2.22). In reverse osmosis the concentration in the permeate can be expressed by the solute flux divided by the volume flux, that is, $C_s^p = \frac{J_s}{J_v}$. Membrane rejection in reverse osmosis is given by:

$$R_s = 1 - \frac{C_s^p}{C_s^f} = 1 - \frac{J_s}{J_v C_s^f} = 1 - \frac{k_s{}^m D_s RT \Delta C_s}{k_w C_s^{fm} D_w (\Delta p - \Delta \pi)} \tag{3.39}$$

Equation (3.39) shows that rejection of a component in reverse osmosis not only depends on the diffusion coefficients of water and solute in the membrane and on their partition coefficients between the membrane and the adjacent solutions, but it is also a function of the applied hydrostatic pressure and approaches asymptotically a maximum value. The rejection disappears when the hydrostatic pressure is equal to the osmotic pressure.

3.4. Principle of Gas Separation

The principle of gas separation is illustrated in Figure 9, which shows two different gas mixtures separated by a membrane. The driving force for the gas to permeate the membrane is a pressure gradient. In gas separation both porous and dense membranes are used as selective barriers. In porous membranes the transport of gases is based on Knudsen diffusion, and in dense solid materials the gas transport is based on a solution-diffusion mechanism. Both Knudsen diffusion and solution-diffusion transport can result in selective transport of gases and thus result in separation of gases. However, the extent of the separation, that is, the separation factor, is much higher in solution-diffusion transport than in Knudsen diffusion.

Figure 9. Schematic illustrating the principle of gas separation

3.4.1. *Gas Separation by Knudsen Diffusion*

Knudsen diffusion can be considered as viscous flow in narrow pores, that is, pores with a diameter that is smaller than the mean free path of the diffusing gas molecules. The mean free path is defined as the average distance a gas molecule travels before it collides with another gas molecule. The mean free path of a gas molecule depends on the nature of the gas, the temperature, and the pressure. It is given by [54]:

$$\lambda = \frac{kT}{\pi d_{gas} p \sqrt{2}} \tag{3.40}$$

where λ is the mean free path of a gas molecule, k the Boltzmann constant, d_{gas} the diameter of the gas molecule, and p the hydrostatic pressure.

The difference between viscous flow and Knudsen diffusion is illustrated in Figure 10.

Figure 10. Schematic illustrating viscous flow and Knudsen diffusion

The figure shows two membrane pores of different diameter with a number of gas molecules. In the pore with the larger diameter the gas molecules have more interaction with each other than with the pore wall since the mean free path of the molecules is much shorter than the pore diameter. In the pore with the smaller diameter the gas molecules have more interactions with the pore wall than with each other. In the case of the larger pores the energy loss during transportation is mainly due to the interaction of the molecules with each other. It is expressed in the viscosity of the solution. Therefore, the flux is referred to as viscous flow in which all molecules are transported with the same rate. In the pores with the smaller diameter the energy loss during the transport of the gas molecule is due to their interaction with the pore wall. The process is similar to diffusion in a homogeneous solid phase and is therefore referred to as Knudsen diffusion. Since molecules of different molar mass have different interaction energies when colliding with the pore wall they are transported with different rates. This can be utilized to separate gases which differ in molecular weight. The mean free path of gases at room temperature and atmospheric pressure is on the order of several nanometers. This means that only membranes with a mean pore size below several nanometers can separate gases by a Knudsen diffusion mechanism. Since the free path of a gas molecule is pressure- and temperature-dependent, as Equation (3.40) indicates, membranes with larger pore diameters can be used when the process is carried out at higher temperature and low pressure.

The flux in Knudsen diffusion can be described by the following relation [55]:

$$J_i = \frac{\pi n r^2 D_i^k \Delta p}{R T \tau \Delta z} \tag{3.41}$$

where J is the flux through the membrane, n the number of pores in the membrane, r the pore radius, Δp the pressure difference across the membrane, Δz the thickness of the membrane, τ the tortuosity factor, and D^k the Knudsen diffusion coefficient.

The Knudsen diffusion coefficient is given by:

$$D_i^k = 0.66 r \sqrt{\frac{8RT}{\pi M_w}} \tag{3.42}$$

Equation (3.42) shows that the Knudsen diffusion coefficient of a gas molecule is inversely proportional to the square root of its molecular weight. Thus, the separation of two gases based on Knudsen diffusion is given by the ratio of the square root of the molecular weights.

$$\alpha_{j,k} \propto \sqrt{\frac{M_k}{M_j}} \tag{3.43}$$

Because of the Knudsen diffusion transport mechanism the selectivity that can be achieved with porous membranes is in general rather low when gases differ only marginally in their molecular mass. Nevertheless, porous membranes are used to separate $^{235}UF_6$ from $^{238}UF_6$. Since the selectivity is only about 1.0043, hundreds of stages are required to obtain significant separation.

3.4.2. *Gas Transport by the Solution-Diffusion Mechanism in a Polymer Matrix*

Significantly higher selectivity can be obtained in homogeneous polymer membranes, where the transport mechanism is based on the solution and diffusion of the various components within the membrane phase. The mass transport in a so-called solution-diffusion membrane is illustrated in Figure 11. It consists of three steps:

1. Sorption of the various components from a feed mixture according to their partition coefficients between the gas and polymer phase.
2. Diffusion of the individual components within the membrane phase according to their activity gradients.
3. Desorption of the components from the membrane in the permeate gas phase.

If viscous flow is excluded the driving force for the mass transport of gases in solution-diffusion membranes is the activity gradient of the permeating components within the membrane phase, which can be related to the difference between the chemical potentials of the component in the feed and the permeate.

Figure 11. Schematic illustrating the three-step transport mechanism in solution-diffusion membranes (μ is the chemical potential, X the mole fraction, C the concentration, p the partial pressure; the subscript i refers to a component, and the superscripts f, p, g, and m to feed, permeate, gas phase, and membrane)

The flux across the membrane can be described again by the phenomenological equation as a function of the gradient of the chemical potential of the permeating component:

$$J_i = -L_i \frac{\mathrm{d}^m \mu_i}{\mathrm{d}z} \tag{3.44}$$

where J is the flux, L a phenomenological coefficient relating the flux to the corresponding driving force, μ the chemical potential, z the directional coordinate perpendicular to the membrane surface, subscript i refers to a component, and

superscript m to the membrane.

The chemical potential in the membrane at the membrane surface is equal to the potential in the adjacent gas phase. The change of chemical potential of a component as function of pressure and composition is given by:

$$\mathrm{d}\,\mu_i = \mu_i^o + \mathrm{d}\,RT\,\ln\,a_i + \overline{V}_i\,\mathrm{d}\,p \tag{3.45}$$

where *a* is the activity, *p* is the hydrostatic pressure, and $\overline{V}$ is the partial molar volume.

Introducing Equation (3.45) into Equation (3.44) gives the flux of component i in the membrane:

$$J_i = -L_i\left(\mathrm{d}\,RT\,\ln\,{}^{\mathrm{m}}a_i + {}^{\mathrm{m}}\overline{V}_i\,\mathrm{d}\,p\right) \tag{3.46}$$

Since in the membrane the pressure is constant (i.e., d*p* = 0) and $\mathrm{d}\,\ln\,a = \frac{\mathrm{d}\,a}{a}$ Equation (3.46) can be written as:

$$J_i = -L_i RT\frac{\mathrm{d}\,{}^{\mathrm{m}}a_i}{{}^{\mathrm{m}}a_i} \tag{3.47}$$

Integration of Equation (3.47) across the membrane gives the flux as function of the activity of component *i* in the membrane at the interface between the feed gas and the permeate gas:

$$J_i = -L_i\frac{RT}{{}^{\mathrm{m}}\overline{a}_i}\frac{{}^{\mathrm{m}}a_i^{\mathrm{p}} - {}^{\mathrm{m}}a_i^{\mathrm{f}}}{\Delta\,z} \tag{3.48}$$

where ${}^{m}\overline{a}_i$ is the average activity of component *i* in the membrane, and superscripts f and p refer to feed side and product side of the membrane.

Since at the interface between the membrane and the gas the chemical potentials of component *i* in the membrane and the gas are equal (i.e., ${}^{m}\mu_i = {}^{g}\mu_i$), the activity of component *i* in the membrane at the interface can be expressed by its activity in the gas. The chemical potential of component *i* in the membrane and in the gas is obtained by integration of Equation (3.45).

In the membrane the partial molar volume of the component can be considered as constant and equal to the molar volume of the condensed gas:

$${}^{\mathrm{m}}\mu_i = \mu_i^o + RT\,\ln\,{}^{\mathrm{m}}a_{\mathrm{g}} + {}^{\mathrm{m}}\overline{V}_i({}^{\mathrm{m}}p - p^o) \tag{3.49}$$

where the superscript o refers to a standard state.

In the gas the partial molar volume is a function of the pressure and must, in accordance with the ideal gas law, be replaced by $\frac{RT}{p}$.

The chemical potential in the gas is then given by:

$${}^{\mathrm{g}}\mu_i = \mu_i^o + RT\,\ln\,{}^{\mathrm{g}}a_{\mathrm{g}} + RT\,\ln\,\frac{p}{p_i^o} = \mu_i^o + RT\,\ln\,\frac{{}^{\mathrm{g}}a_i p}{p_i^o} \tag{3.50}$$

Since the chemical potentials in the membrane and the gas at the gas membrane interface are equal:

$${}^{\mathrm{g}}\mu_i = {}^{\mathrm{m}}\mu_i = RT\,\ln\,\frac{{}^{\mathrm{g}}a_i p}{p_i^o} = RT\,\ln\,{}^{\mathrm{m}}a_i + {}^{\mathrm{m}}\overline{V}_i({}^{\mathrm{m}}p - p^o) = \frac{{}^{\mathrm{g}}a_i p}{p_i^o} = {}^{\mathrm{m}}a_i\,\exp\,\frac{{}^{\mathrm{m}}\overline{V}_i({}^{\mathrm{m}}p - p^o)}{RT} \tag{3.51}$$

where p_i° is the saturation pressure of the gas.

It can be shown that the exponential term in Equation (3.51) even at high pressure is always close to 1. Therefore, the activity of component *i* at the interface with the gas can be expressed by:

$${}^{\mathrm{m}}a_i^{\mathrm{f}} = \frac{{}^{\mathrm{g}}a_i^{\mathrm{f}}p^{\mathrm{f}}}{p_i^o}\ \text{and}\ {}^{\mathrm{m}}a_i^{\mathrm{p}} = \frac{{}^{\mathrm{g}}a_i^{\mathrm{p}}p^{\mathrm{p}}}{p_i^o} \tag{3.52}$$

where the superscripts *f and p* refer to feed and permeate side of the membrane.

The activity of component *i* in the membrane and in the gas can be related to its concentration in the membrane and its molar fraction in the gas by:

$${}^{\mathrm{m}}a_i = {}^{\mathrm{m}}X_i\,{}^{\mathrm{m}}\gamma_i\ \text{and}\ {}^{\mathrm{g}}a_i = \frac{X_i\varphi_i}{p_i^0} \tag{3.53}$$

where *X* is the molar fraction, γ the activity coefficient, φ the fugacity coefficient, and superscripts m, g, and o refer to the membrane, the gas phase, and the saturation pressure.

Introducing Equations (3.52) and (3.53) into Equation (3.48) leads to:

$$J_i = -L_i \frac{RT}{{}^{m}X_i\,{}^{m}\gamma_i p_i^0} \frac{X_i^p p^p \varphi_i^p - X_i^f p^f \varphi_i^f}{\Delta z} \tag{3.54}$$

where L is a phenomenological coefficient, X the molar fraction in the gas, p the pressure, φ the fugacity coefficient, ${}^{m}X_i$ and ${}^{m}\gamma_i$ are the average molar fraction and the average activity coefficient of component i in the membrane, Δz is the thickness of the membrane, superscripts p, f, and o refer to permeate, feed, and saturation pressure, and subscript i refers to a component.

Introducing the relation between the phenomenological coefficient and the diffusion coefficient as expressed in Equation (2.18), that is, $L_i = \frac{D_i C_i}{RT}$, the relation between the molar fraction and the concentration given by ${}^{m}C_i = X_i \frac{{}^{m}\rho}{M_i}$, and assuming that to a first approximation $\varphi_i^p = \varphi_i^f$ Equation (3.54) becomes:

$$J_i = -D_i \frac{\varphi_i\,{}^{m}\rho}{{}^{m}\gamma_i\, p_i^0 M_i} \frac{X_i^p p^p - X_i^f p^f}{\Delta z} \tag{3.55}$$

Introducing a sorption coefficient given by $k_i = \frac{\varphi_i\,{}^{m}\rho}{{}^{m}\gamma_i\, p_i^0 M_i}$ into Equation (3.55) leads to:

$$J_i = -D_i k_i \frac{X_i^p p^p - X_i^f p^f}{\Delta z} \tag{3.56}$$

where D is the diffusion coefficient in the membrane, k_i the gas sorption coefficient of the membrane, ρ the density, M the molecular weight, and subscript i refers to a component.

The product of diffusion and sorption coefficient is the membrane permeability given by $P_i = D_i k_i$. Introducing the permeability P_i into Equation (3.56) gives the flux J_i of a component through the membrane as a function of its molar fractions in the feed and permeate X_i^f and X_i^p, its fugacity coefficient φ_i, its permeability in the membrane P_i, the membrane thickness Δz, and the pressures in the feed and permeate p^f and p^p.

$$J_i = -P_i \frac{X_i^p p^p - X_i^f p^f}{\Delta z} \tag{3.57}$$

In deriving Equation (3.57) several assumptions have been made which are generally valid for permanent gases. However, the assumption that the diffusion and the solubility coefficient are independent of concentration and pressure is not valid for easily condensable vapors. In permeation of organic vapors, the diffusion coefficient may vary by several orders of magnitude with the concentration of the permeating component in the membrane.

For the relationship between the diffusion coefficient and the concentration of the diffusing component different equations accounting for dual sorption or free volume and structural changes of the polymer are discussed in the literature. For gas and especially vapor permeation it is generally not possible to predict the mass transport behavior of various components in a mixture from single-component measurements.

For a practical application the separation efficiency of the membrane is a crucial parameter. In gas permeation the separation efficiency of a membrane is expressed by its selectivity and/or its separation factor. The selectivity of a membrane for various components of a mixture is defined by the ratio of the permeabilities. For a binary mixture of components k and j, the selectivity is:

$$S_{j,k}^P = \frac{P_j}{P_k} \tag{3.58}$$

where $S^P_{j,k}$ is the permeation selectivity of a membrane for the components j and k, and P_j and P_k are their permeabilities.

The permeation selectivity can be split into two terms, namely, the selectivity due to different diffusion coefficients of the components of the gas mixture and that due to their solubility in the membrane:

$$S_{j,k}^P = S_{j,k}^D S_{j,k}^k \tag{3.59}$$

where $S_{j,k}^D$ and $S_{j,k}^k$ are the diffusivity and solubility selectivity of a membrane for components j and k.

The selectivity is a useful parameter to characterize a membrane. For the design of a membrane plant, however, the separation factor is more useful. For a binary mixture the separation factor is defined by:

$$\alpha_{j,k} = \frac{X_j^p}{X_j^f} \frac{X_k^f}{X_k^p} \tag{3.60}$$

where α is the separation factor, X the mole fraction, subscripts k and j refer to the two components, and superscripts f and p refer to feed and the permeate.

The separation factor is defined to be always greater than 1. It is related to the membrane selectivity by:

$$\alpha_{j,k} = S_{j,k} \frac{\frac{X_j^{\mathrm{p}} p^{\mathrm{p}}}{p^{\mathrm{f}}} - X_j^{\mathrm{f}}}{\frac{X_k^{\mathrm{p}} p^{\mathrm{p}}}{p^{\mathrm{f}}} - X_k^{\mathrm{f}}} \frac{X_k^{\mathrm{f}}}{X_j^{\mathrm{f}}} \tag{3.61}$$

where *S* is the selectivity for a binary mixture, *p* the pressure, *X* the molar fraction, superscripts f and p refer to feed and the permeate, and subscripts *k* and *j* to the components in the mixture. The separation factor is always smaller than the selectivity and when the pressure ratio of feed to permeate becomes infinitely high:

$$\lim_{\frac{p^{\mathrm{p}}}{p^{\mathrm{f}}} \to 0} a_{j,k} = S_{j,k} \tag{3.62}$$

In vapor separation, the factor α is normally a function of the feed concentration.

3.5. Principle of Pervaporation

Pervaporation is a membrane process in which the permeation of certain components through a membrane from a liquid feed mixture into a vapor phase is combined with the evaporation of these components. The principle of the process is illustrated in Figure 12.

Figure 12. Schematic illustrating the principle of pervaporation showing an asymmetric membrane with a dense solution-diffusion barrier layer

The membranes and transport mechanism of a component through these membranes in pervaporation are the same as in gas separation. The driving force for transport is the chemical potential gradient of the permeating components in the membrane. The chemical potential gradient in the membrane can be related to the partial vapor pressures in the liquid and vapor phases. To establish a partial pressure difference of a component in the liquid and the vapor phase, generally, a vacuum is applied at the permeate side of the membrane. But differences in the partial pressure of a component can also be established by using a sweeping gas on the permeate side or by a temperature difference between the liquid feed and the vapor.

Mass transport in a pervaporation membrane can be described by the same mathematical relations as gas transport with the exception that the chemical potential in the membrane on the feed side of the membrane is not expressed by the molar fraction, the hydrostatic pressure, and the fugacity coefficient, but by the molar fraction and the activity coefficient in the liquid phase, and the saturation pressure of the component.

Thus, mass transport in pervaporation is given by:

$$J_i = -D_i k_i \frac{X_i^{\mathrm{p}} p^{\mathrm{p}} - X_i^{\mathrm{l}} \gamma_i^{\mathrm{l}} p_i^{\mathrm{o}}}{\Delta z} \tag{3.63}$$

where D_i is the diffusion coefficient of component *i* in the membrane, k_i the sorption coefficient of component *i* into the membrane matrix, *X* the molar fraction, *p* the pressure, γ the activity coefficient, subscripts *j* and *k* refer to components of the mixture, and the superscripts o, l, and *p* to saturation pressure, feed, and permeate, respectively.

Equation (3.63) describes the permeation flux of a component *i* as a function of the feed and permeate mixture composition and its diffusivity and solubility in the membrane, which can easily be determined by independent measurements. The practical application of Equation (3.63), however, is rather limited since the diffusion coefficient and the distribution coefficient are not constant but depend strongly on the concentration of the permeating component in the membrane. This dependency must be determined experimentally and may be different for different membrane materials and vapors.

The product of diffusion and distribution coefficient is referred to as permeability coefficient, and the ratio of the permeability coefficients of two components determine the membrane selectivity for the two components.

$$D_i k_i = P_i \tag{3.64}$$

$$S_{j,k} = \frac{P_j}{P_k} \tag{3.65}$$

where *P* is the permeability of the membrane, *S* the membrane selectivity, and *j* and *k* refer to the components of the mixture.

The separation factor in pervaporation of a two-component mixture is given by:

$$\alpha_{j,k} = \frac{X_j^{\mathrm{p}} X_k^{\mathrm{p}}}{X_j^{\mathrm{l}} X_k^{\mathrm{l}}} = S_{j,k} \frac{X_j^{\mathrm{p}} \varphi_j^{\mathrm{p}} - X_j^{\mathrm{l}} \gamma_j^{\mathrm{l}} p_j^{\mathrm{o}}}{X_k^{\mathrm{p}} \varphi_k^{\mathrm{p}} - X_k^{\mathrm{l}} \gamma_k^{\mathrm{l}} p_k^{\mathrm{o}}} \frac{X_k^{\mathrm{l}}}{X_j^{\mathrm{l}}} \tag{3.66}$$

where α is the separation factor, *S* the membrane selectivity, *X* the molar fraction, *p* the pressure, and γ the activity coefficient, subscripts *j* and *k* refer to components of the mixture, and superscripts o, l, and p to saturation pressure, feed, and permeate, respectively.

In pervaporation the partial pressure of the components on the permeate side is kept as low as possible by either using a sweeping gas or more commonly by applying a vacuum, i.e., $X_j^{\mathrm{p}} p^{\mathrm{p}} << X_j^{\mathrm{l}} \gamma_j^{\mathrm{l}} X_j^{\mathrm{0}}$ and $X_k^{\mathrm{p}} p^{\mathrm{p}} << X_k^{\mathrm{l}} \gamma_k^{\mathrm{l}} X_k^{\mathrm{0}}$. For a pervaporation experiment using a vacuum the separation factor is to a first approximation:

$$\lim_{p^{\mathrm{p}} \to 0} \alpha_{j,k} = S_{j,k} \frac{\gamma_j^{\mathrm{l}} p_j^{\mathrm{0}}}{\gamma_k^{\mathrm{l}} p_k^{\mathrm{0}}} \tag{3.67}$$

Thus, the separation factor consists of two terms: $S_{j,k}$, which represents the membrane selectivity, and the thermodynamic liquid/vapor equilibrium $\frac{\gamma_j^{\mathrm{l}} p_j^{\mathrm{0}}}{\gamma_k^{\mathrm{l}} p_k^{\mathrm{0}}}$, which represents the separation that would be achieved by distillation. In pervaporation the membrane selectivity can increase or decrease the distillation selectivity and eventually push the overall separation factor in the opposite direction.

3.6. Principle of Dialysis

Dialysis is carried out under isobaric conditions, and there is no temperature or electrical potential gradient. The principle of the process is depicted in Figure 13.

Figure 13. Schematic illustrating the principle of dialysis with two neutral components of different size

The schematic drawing shows a liquid solution containing a solvent and molecular components of different molecular weight or size, referred to as feed solution separated by a membrane from the solvent referred to as dialysate or “stripping” solution. Due to the driving force of a concentration difference the components will diffuse through the membrane from the feed solution to the dialysate. Their fluxes through the membrane and thus their separation is determined by their diffusion rate in the membrane matrix.

There are different forms of dialysis depending on the constituents of the feed solution and the structure of the membrane. The simplest form is the dialysis of neutral components.

3.6.1. *Dialytic Mass Transport of Neutral Components*

The mass flux in dialysis of a mixture, which contains neutral components only, can be expressed by the phenomenological equation, which can then be related to Fick's law by several approximations.

For a membrane and a feed solution with uncharged components the flux of a component at constant temperature and pressure is given by:

$$J_i = -L_i \frac{\mathrm{d}\,\mu_i}{\mathrm{d}\,z} = -L_i RT \frac{\mathrm{d}\ \ln\ a_i}{\mathrm{d}\,z} = -L_i RT \mathrm{d}\ \ln\ C_i \gamma_i \tag{3.68}$$

where J is the flux, L a phenomenological coefficient, μ the chemical potential, a the activity, C the concentration, γ the activity coefficient, z the directional coordinate perpendicular to the membrane, and the subscript i refers to a component.

Assuming that the activity coefficient is 1 and replacing the phenomenological coefficient by the diffusion coefficient according to Equation (2.18) leads to:

$$J_i = L_i \frac{RT}{C_i} \frac{\mathrm{d}\,C_i}{\mathrm{d}\,z} = D_i \frac{\mathrm{d}\,C_i}{\mathrm{d}\,z} \tag{3.69}$$

Equations (3.68) and (3.69) indicate that the mass transport in dialysis with feed solutions containing neutral components can be described adequately by Fick's law if there is no coupling of fluxes and if the activity coefficient of the components in the membrane is unity, which is the case in many practical applications.

3.6.2. *Dialytic Mass Transport of Electrolytes in a Membrane without Fixed Ions*

If feed solutions with charged components (i.e., electrolyte solutions) are treated by dialysis, the electroneutrality requirement must be satisfied. For a system consisting of a membrane and solutions with various ions the electroneutrality condition requires:

$$\sum_{\mathrm{a}} |\, z_{\mathrm{a}} \,|\, C_{\mathrm{a}} = \sum_{\mathrm{c}} z_{\mathrm{c}} C_{\mathrm{c}} \tag{3.70}$$

where z is the valance, C the concentration, and subscripts a and c refer to anion and cation, respectively.

If the membrane contains fixed ions they must be included in the electroneutrality requirement. The fixed charges are negative in a cation-exchange membrane and positive in an anion-exchange membrane. If there is no electrical current the conservation of electrical charge requires that cations and anions move in the same direction. Hence:

$$\sum_{\mathrm{a}} |\, z_{\mathrm{a}} \,|\, J_{\mathrm{a}} = \sum_{\mathrm{c}} z_{\mathrm{c}} J_{\mathrm{c}} \tag{3.71}$$

The concentration of the electrolyte (e.g., a single salt) is related to that of the ions by:

$$C_a = \alpha \nu_a C_s \text{ and } C_c = \alpha \nu_c C_s \tag{3.72}$$

where α is the degree of dissociation of the electrolyte, ν a stoichiometric coefficient, and subscript s refers to the electrolyte.

The stoichiometric coefficient relates the number of ions to that of the salt molecules. For a completely dissociated monovalent salt such as NaCl α and ν are 1. For a salt such as $CaCl_2$ ν_c is 1 and ν_a is 2.

In an electrolyte solution the fluxes of the ions are the result of an electrochemical potential gradient driving force. The electrochemical potential of ions is related to that of the electrolyte by [56]:

$$\eta_s = \nu_a \eta_a + \nu_c \eta_c \tag{3.73}$$

where η is the electrochemical potential.

Since in dialysis no external potential and no hydrostatic pressure difference is applied the flux of the ions can be described as a function of the diffusion coefficient and the concentration gradient by Equation (3.69) if the activity coefficients are assumed to be 1. However, the fluxes of the ions are related to each other by the electroneutrality requirement and the conservation of charges, with the consequence that in diffusion of an electrolyte which consists of a cation and an anion with significantly different diffusivities the faster moving ion will cause a minute charge imbalance and thus an electrical potential gradient. This potential gradient is referred to as diffusion potential, and although it may be very small it will slow down the faster diffusing ion and speed up the slower ion so that both ions diffuse with the same velocity.

The flux of the completely dissociated monovalent electrolyte is related to that of the ions by:

$$J_s = J_a = J_c = -D_s \frac{dC_s}{dz} = -D_a |z_a| \frac{dC_a}{dz} = -D_c z_c \frac{dC_c}{dz} \tag{3.74}$$

where *J* is the flux, *C* the concentration, *D* the diffusion coefficient, *z* the valence or the directional coordinate, and subscripts s, a, and c refer to salt, anion, and cation, respectively.

Rearranging Equation (3.74) under consideration of Equation (3.73) gives the diffusion coefficient of the salt as a function of the diffusion coefficients of the cations and anions:

$$D_s = \frac{D_a D_c (|z_a| + z_c)}{D_a |z_a| + D_c z_c} \tag{3.75}$$

Combination of Equations (3.74) and (3.75) gives the salt and ion fluxes for a completely dissociated monovalent salt at constant temperature and pressure in an ideal solution, that is, the activity coefficients are 1:

$$J_s = \frac{D_a D_c (|z_a| + z_c)}{D_a |z_a| + D_c z_c} \frac{dC_s}{dz} \tag{3.76}$$

where *J* is the flux, *C* the concentration, *D* the diffusion coefficient; *z* the valence or the directional coordinate, and subscripts s, a, and c refer to salt, anion, and cation, respectively.

Equation (3.76) describes the flux of an electrolyte as a function of the diffusion coefficients of the individual ions. This is the consequence of the electroneutrality requirement for the transport of ions which have different diffusivities. Because the faster moving ion will cause the buildup of a minute electrical potential gradient which will slow down the faster ion and speed up the slower ion, at steady state both ions move with the same velocity. Therefore, an average diffusion coefficient for each ion can be defined to describe the fluxes of the different ions, which are coupled by the conservation of charges and the electroneutrality condition. The average diffusion coefficient $\overline{D}$ is given by:

$$\overline{D}_c = \overline{D}_a = D_s = \left(\frac{D_a D_c |z_a| + z_c}{D_a |z_a| + z_c D_c} \right) \tag{3.77}$$

Equations (3.76) and (3.77) respectively describe the transport of a single electrolyte under the driving force of a concentration or activity gradient through a membrane that does not carry any fixed charges. In this case all ions of the electrolyte are transported in the same direction even if their diffusion coefficients are quite different. The situation, however, becomes more complex if a feed solution contains more than one electrolyte and if the membrane carries fixed charges. In this case certain ions may be transported against their concentration gradient.

3.6.3. *Dialysis of Electrolytes in Ion-Exchange Membranes*

The fluxes of ions through ion-exchange membranes in dialysis are even more complex and may result in transport of certain ions against their concentration gradient, as illustrated in Figure 14. Figure 14a shows countercurrent coupled transport of H^+ and Na^+ ions through a cation-exchange membrane. This process is referred to as Donnan dialysis. Figure 14b depicts cocurrent transport of H^+ ions and Cl^- ions through an anion-exchange membrane.

Figure 14. Schematic illustrating the fluxes across an ion-exchange membrane which separates two electrolyte solutions of different concentrations containing HCl and NaCl. a) Shows the fluxes through a cation-exchange membrane and represents countercurrent coupled flux, i.e., Donnan dialysis, and b) shows the fluxes through an anion-exchange membrane and represents cocurrent coupled transport, i.e., diffusion dialysis

In Donnan dialysis with a strictly permselective ion-exchange membrane the flux of the co-ion (i.e., in Figure 14a the Cl^- ions) is 0 and the fluxes of the counterions (i.e., the Na^+ and H^+ ions) are equal but in opposite directions. Thus, there is no net transport of electrical charges across the membrane, that is, there is no electrical current and the conservation of charges is fulfilled. For the system illustrated in Figure 14a the transport of a counterion (i.e., the Na^+ ion) is the result of a flux of another counterion (i.e., the H^+ ion) in the opposite direction under the driving force of a concentration gradient. Since no co-ions (i.e., Cl^- ions) can permeate the cation-exchange membrane, the flux of the H^+ ions must be identical to that of the Na^+ ions. The fluxes are given by:

$$J_{H^+} = -2\left(\frac{L_{H^+}L_{Na^+}}{L_{H^+}+L_{Na^+}}\right)\frac{RT\,\mathrm{d}\ln a_{H^+}}{\mathrm{d}z} = J_{Na^+} \tag{3.78}$$

The transport of Na^+ ions due to the H^+ ion flux results in a buildup of an activity gradient of the Na^+ ions, which causes a backtransport. When the Na^+ ion flux caused by the activity gradient is identical to that caused by the H^+ ion flux equilibrium is reached and there will be no further ion transport through the membrane. This equilibrium, which is referred to as Donnan equilibrium, is given by:

$$\mathrm{d}\ln a_{H^+} = \mathrm{d}\ln a_{Na^+} \tag{3.79}$$

The Donnan equilibrium between two solutions with different Na^+ ion and H^+ ion concentrations separated by a permselective cation-exchange membrane is:

$$\frac{a'_{Na^+}}{a''_{Na^+}} = \frac{a'_{H^+}}{a''_{H^+}} \tag{3.80}$$

where ′ and ″ refer to the two solutions separated by the membrane.

Donnan dialysis plays an important role in water softening, and Equation (3.80) determines the minimum and maximum concentrations of a counterion which can be achieved by a given flux of another counterion.

Cocurrent coupled transport is illustrated in Figure 14b, which shows a solution containing a mixture of a salt (NaCl) and an acid (HCl), separated by an anion-exchange membrane from a solution containing no salt. The Cl^- ion concentration in the solution containing the salt – acid mixture is assumed to be much higher than in the solution containing only the acid. Due to a concentration gradient the Cl^- ions permeate the anion-exchange membrane towards the solution containing only the acid. Because of the electroneutrality requirement an anion can permeate the membrane only when accompanied by a cation. The anion-exchange membrane, however, is impermeable to cations such as Na^+ ions but it is to some extent permeable to H^+ ions because protons are transported in aqueous solution and also in highly swollen ion-exchange membranes by a different transport mechanism. The Cl^- ion concentration gradient across the membrane acts as driving force for the transport of H^+ ions, which are transported against their concentration gradient. The minimum concentration of the acid in the salt solution and the maximum concentration of the acid that can be achieved is given when the activity gradients of the H^+ ion and the Cl^- ion across the membrane are identical. The cocurrent transport of an anion with a H^+ ion is of practical importance for the recovery of acids from spent pickling solutions containing the acid in a mixture with salts.

3.7. Principle of Electrodialysis

The principle of the electrodialysis is illustrated in Figure 15.

Figure 15. Schematic illustrating the principle of electrodialysis

In electrodialysis cation-exchange membranes carrying fixed negative electric charges and anion-exchange membranes carrying positive fixed charges are placed in alternating series between two electrodes. Cation- and anion-exchange membranes form individual cells filled with an electrolyte-containing feed solution. If an electric potential between the electrodes is established the cations migrate towards the negatively charged cathode while the anions migrate towards the positively charged anode. Cations can easily permeate a cation-exchange membrane but are retained by an anion-exchange membrane, while anions permeate the anion-exchange membrane but are retained by the cation-exchange membrane. Thus, ions are accumulated in alternating cells to form the concentrate solution while the other cells are depleted and form the diluate solution.

In electrodialysis mass transport is the result of an electrochemical potential gradient across the membrane, that is, a gradient in the chemical and electrical potential. An electrical potential driving force acts on charged components only and in such a way that negatively charged components (anions) migrate in the direction towards the positively charged anode and the positively charged cations migrate towards the negatively charged cathode, that is, cations and anions move in opposite directions.

To describe the mass transport of a salt in an aqueous solution through a membrane which is used as frame of reference three independent fluxes must be considered: the flux of the cations, the flux of anions, and the flux of the solvent. The transport of ions result from an electrochemical potential difference, and the transport of the solvent through the membrane from osmotic effects and coupling with the fluxes of the ions. Under certain conditions the solvent flux can be significant and must be taken into account.

Ion-exchange membranes carry positive or negative electrical charges fixed to a solid matrix and are therefore permselective as far as the transport of ions is concerned, that is, the cation-exchange membranes are preferentially permeable to cations and the anion-exchange membranes are preferentially permeable to anions.

Mass transport in electrodialysis can be described by a phenomenological equation giving the flux of the individual components by:

$$J_i = \sum_k L_{ik} \frac{\mathrm{d}\eta_k}{\mathrm{d}z} = \sum_k L_{ik} \left(RT \frac{\mathrm{d} \ln a_k}{\mathrm{d}z} + z_i F \frac{\mathrm{d}\varphi}{\mathrm{d}z} \right) \tag{3.81}$$

Assuming an ideal solution, that is, one in which the activity of a component is identical to its concentration and without kinetic coupling between individual components, and expressing the phenomenological coefficient by the Fick's diffusion coefficient, Equation (3.81) becomes identical to the Nernst – Planck flux equation, which is given by [57]:

$$\mathrm{J_i} = -D_i \left(\frac{\mathrm{d}C_i}{\mathrm{d}z} + \frac{\mathrm{z_i} F C_i}{RT} \frac{\mathrm{d}\varphi}{\mathrm{d}z} \right) \tag{3.82}$$

where D_i is the diffusion coefficient of component *i* with reference to the membrane.

The first term in Equation (3.82) $D_i \frac{\mathrm{d}C_i}{\mathrm{d}z}$ represents the diffusion, and the second term $D_i \frac{z_i C_i F}{RT} \frac{\mathrm{d}\varphi}{\mathrm{d}z}$ the migration.

Thus, the Nernst – Planck equation is an approximation of the more general phenomenological equation.

In ion-exchange membrane separation processes such as electrodialysis the flux of the cations through the cation-exchange membrane and the flux of the anions through the anion-exchange membrane are interdependent because of the electroneutrality requirement in the solution between the membranes, as can easily be seen when considering the electrodialysis of a solution of a monovalent single electrolyte such as NaCl. If strictly permselective membranes are assumed the fluxes of the cations through the cation-exchange membrane and of the anions through the anion-exchange membrane are equal. Thus, in a solution containing a monovalent, completely dissociated electrolyte such as NaCl and strictly permselective membranes it is [22, 56]:

$$^{\mathrm{cm}}J_{\mathrm{Na}^+} = {}^{\mathrm{am}}J_{\mathrm{Cl}^-} = J_{\mathrm{s}} = -2 \left(\frac{^{\mathrm{cm}}D_{\mathrm{Na}^+} \, {}^{\mathrm{am}}D_{\mathrm{Cl}^-}}{^{\mathrm{cm}}D_{\mathrm{Na}^+} + {}^{\mathrm{am}}D_{\mathrm{Cl}^-}} \right) \left(\frac{RT}{^{\mathrm{im}}C_i} \frac{\mathrm{d}\,^{\mathrm{im}}C_i}{\mathrm{d}z} + F \frac{\mathrm{d}\varphi}{\mathrm{d}z} \right) \tag{3.83}$$

where $^{\mathrm{cm}}J_{\mathrm{Na+}}$ and $^{\mathrm{am}}J_{\mathrm{Cl-}}$ are the fluxes of Na^+ ions through the cation-exchange membrane and of Cl^- ions through the anion-exchange membrane, $^{\mathrm{cm}}D_{\mathrm{Na+}}$ and $^{\mathrm{am}}J_{\mathrm{Cl-}}$ are the diffusion coefficients for the transport of Na^+ and Cl^- ions through the corresponding membrane, subscript *i* refers to cation or anion, and superscript *i*m to cation- or anion-exchange membrane.

3.7.1. *Electrical Current and Ion Fluxes*

In electrodialysis it is assumed that the total current through the membrane is carried by ions only:

$$i = \frac{I}{A} = F \sum_i |z_i| J_i \tag{3.84}$$

where *i* is the current density, *I* the current, *A* the membrane surface, *F* the Faraday constant, *J* the flux, *z* the valence, and subscript *i* refers to cations and anions.

The current density *i* can be related to the specific conductivity κ by:

$$i = \kappa \frac{\mathrm{d}\varphi}{\mathrm{d}z} \tag{3.85}$$

where κ is the specific conductivity, φ the electrical potential, and *z* the directional coordinate.

The specific conductivity κ can be expressed by the specific electrical resistance, the equivalent conductivity, the ion migration velocity, or the ion diffusivity:

$$\kappa = \frac{1}{\rho} = \sum_i |z_i| C_i \lambda_i = F \sum_i |z_i| C_i u_i = F^2 \sum_i |z_i| C_i \frac{D_i}{RT} \tag{3.86}$$

where ρ is the specific resistance, *C* the concentration, *F* the Faraday constant, λ the equivalent conductivity, *u* the ion migration velocity, *D* the ion diffusion coefficient, *R* the gas constant, *T* the absolute temperature, and subscript *i* refers to anions and cations.

Introducing Equations (3.85) and (3.86) into Equation (3.84) and rearranging leads to:

$$i = F \sum_i |z_i| J_i = F^2 \sum_i z_i^2 \frac{C_i D_i}{RT} \left(\frac{RT}{z_i C_i F} \frac{\mathrm{d}C_i}{\mathrm{d}z} + \frac{\mathrm{d}\varphi}{\mathrm{d}z} \right) \tag{3.87}$$

where *i* is the current density, *C* the concentration, *F* the Faraday constant, φ the electrical potential, *z* the valence, *D* the ion diffusivity, *R* the gas constant, *T* the absolute temperature, and subscript *i* refers to anions and cations.

The term $\frac{RT}{z_i C_i F} \frac{\mathrm{d}C_i}{\mathrm{d}z}$ has the dimensions of an electrical potential gradient and represents the concentration potential which is established between two electrolyte solutions of different concentrations. In electrodialysis this potential is established between the concentrate and the diluate solution. It represents an electromotive force which has to be overcome by the applied electrical potential.

3.7.2. *Transport Number and Membrane Permselectivity*

In an electrolyte solution the current is carried by both ions. However, cations and anions usually carry different portions of the overall current. In ion-exchange membranes the current is carried preferentially by the counterions. The fraction of the current that is carried by a certain ion is expressed by the ion transport number, which is given by:

$$T_i = \frac{|z_i| J_i}{\sum_j |z_j| J_j} \tag{3.88}$$

where T_i is the transport number of component *i*, J_i its flux, z_i its valence, and subscript *j* refers to all ions involved in the charge transport.

The transport number T_i indicates the fraction of the total current that is carried by ion *i*; the sum of the transport numbers of all ions in a solution is 1.

The membrane permselectivity is an important parameter for determining the performance of a membrane in a certain ion-exchange membrane separation process. It describes the degree to which a membrane passes an ion of one charge and retains an ion of the opposite charge. The permselectivity of cation- and anion-exchange membranes can be defined [58] by the following relations:

$$\Psi^{\mathrm{cm}} = \frac{T_{\mathrm{c}}^{\mathrm{cm}} - T_{\mathrm{c}}}{T_{\mathrm{a}}} \tag{3.89}$$

$$\Psi^{\mathrm{am}} = \frac{T_{\mathrm{a}}^{\mathrm{am}} - T_{\mathrm{a}}}{T_{\mathrm{c}}} \tag{3.90}$$

where Ψ is the permselectivity of a membrane, *T* the transport number, superscripts cm and am refer to cation- and anion-exchange membranes, and subscripts c and a to cation and anion, respectively.

The permselectivity of an ion-exchange membrane relates the transport of electric charges by a specific counterion to the total transport of electric charges through the membrane and the transport number of the ion in the solution. An ideal permselective cation-exchange membrane would transmit positively charged ions only, that is, for a transport number of a counterion in a cation-exchange membrane of $T_c^{cm} = 1$ the permselectivity $\Psi^{cm} = 1$. The permselectivity approaches zero when the transport number within the membrane is identical to that in the electrolyte solution, that is, for $T_c^{cm} = T_c$, $\Psi^{cm} = 0$. For the anion-exchange membrane, the corresponding relation holds.

The transport number of a certain ion in the membrane is proportional to its concentration in the membrane, which again is a function of its concentration in the solutions in equilibrium with the membrane phase, due to Donnan exclusion, as discussed above. The concentration of a co-ion in an ion-exchange membrane can be calculated from the Donnan equilibrium, which is given in Equation (2.29). For a monovalent salt and a dilute salt solution and assuming the activity coefficients of the salt in the membrane and the solution to be 1, the co-ion concentration is given to a first approximation by:

$${}^{m}C_{\mathrm{co}} = \frac{{}^{s}C_{\mathrm{s}}^2}{C_{\mathrm{fix}}} \tag{3.91}$$

where *C* is the concentration, subscripts co, s, and fix refer to co-ion, salt, and fixed ion of the membrane, and superscripts s and m to membrane and solution.

Equation (3.91) indicates that the co-ion concentration in the membrane increases with increasing solution salt concentration, and the membrane permselectivity decreases correspondingly.

3.7.3. *Membrane Counterion Permselectivity*

The transport number of different counterions in the membrane can be quite different. The transport rates of ions are determined by their concentration and their mobility in the membrane. The concentration of the counterions is always close to the concentration of the fixed charges of the membrane. The mobility of the ions in the membrane depends mainly on the radius of the hydrated ions and the membrane structure. The mobilities of different ions in an aqueous solution do not differ

very much from each other. An exception are the H^+ and OH^- ions, the mobility of which is higher than that of other ions by a factor of about 5 to 6. The exceptionally high mobility of the H^+ ion can be explained by the transport mechanism of protons. Salt ions move with their hydration shell through the solution. Protons interact with water dipoles and form hydronium ions, which are transported in the membrane mostly by a so-called tunnel mechanism. The transport mechanism of the proton is also the reason for the high permeability of anion-exchange membranes to protons, while these membranes generally have a very low permeability for salt cations. The same mechanism as that described here for the transport of protons also holds for the transport of hydroxide ions, and thus the permeability of hydroxide ions in a cation-exchange membrane is much higher than that of other salt anions.

The permselectivity of an ion-exchange membrane for different salt counterions is determined by the concentration and the mobility of the different ions in the membrane. The concentrations of the different counterions in the ion-exchange membrane are generally also different. A typical counterion-exchange sequence of a cation-exchange membrane containing SO_3^- groups as fixed charges is:

$$Ba^{2+} > Pb^{2+} > Sr^{2+} > Ca^{2+} > Mg^{2+} > Ag^+ > K^+ > NH_4^+ > Na^+ > Li^+$$

A similar counterion-exchange sequence is obtained for anions in an anion-exchange membrane containing quaternary ammonium groups as fixed charges [22, 56]:

$$I^- > NO_3^- > Br^- > Cl^- > SO_4^{2-} > SO_4^{2-} > F^-$$

3.7.4. *Water Transport in Electrodialysis*

Water transport in electrodialysis from the diluate to the concentrate process stream can effect the process efficiency significantly. If a convective flux as a result of pressure differences between flow streams can be excluded there are still two sources for the transport of water from the diluate to the concentrate solution. The first is the result of osmotic pressure differences between the two solutions, and the second is due to electroosmosis, which results from the coupling of water to the ions being transported through the membrane due to the driving force of an electrical potential.

Each of the two fluxes may be dominant, depending on the permselectivity of the ion-exchange membrane, the concentration gradient, and the current density. In a highly permselective membrane and for moderate differences in salt concentration in the two solutions separated by the membrane, the electroosmotic flux dominates and is generally much higher than the osmotic solvent flux. In electrodialysis the water flux due to electroosmosis can be expressed by a solvent transport number, which gives the number of water molecules transported by one ion:

$$J_w = {}^mT_w \sum_i J_i \tag{3.92}$$

where ${}^mT_w$ is the water transport number, J_w the water flux, and J_i the flux of ions through a given membrane.

The water transport number is thus:

$${}^mT_w = \frac{J_w}{\sum_i J_i} \tag{3.93}$$

The water transport number is the number of water molecules transferred by one ion through a given membrane. It depends on the membrane and on the electrolyte, that is, on the size of the ions, their valence, and their concentration in the solution. In aqueous salt solutions and commercial ion-exchange membranes the water transport number is on the order of 4 to 8, that is, 1 mol of ions transports ca. 4 – 8 mol of water through a typical commercial ion-exchange membrane.

3.8. Electrodialysis With Bipolar Membranes

Electrodialysis with bipolar membranes has gained increasing attention as an efficient tool for the production of acids and bases from the corresponding salts [59]. This process is economically attractive and has many potential applications. A typical arrangement of an electrodialysis stack with bipolar membranes is illustrated in Figure 16, which shows the production of an acid and a base from the corresponding salt in a repeating cell unit which consists of three individual cells containing the salt solution, the acid, and the base, and three membranes (a cation-exchange, an anion-exchange, and a bipolar membrane); 50–100 repeating cell units may be placed between two electrodes in industrial-scale stacks.

Figure 16. Schematic illustrating acid and base production from the corresponding salt by electrodialysis with bipolar membranes

The key element in electrodialysis with bipolar membranes is the bipolar membrane itself. Its function is illustrated in Figure 17, which shows a bipolar membrane consisting of an anion- and a cation-exchange layer arranged in parallel between two electrodes. If a potential difference is established between the electrodes, all charged components will be removed from the interface between the two ion-exchange layers. If only water is left between the membranes, further transport of electrical charges can be accomplished only by protons and hydroxyl ions, which have a concentrations of about 10^{-7} mol L^{-1} in completely deionized water. Protons and hydroxyl ions removed from the interface between the cation- and anion-exchange membranes are replenished because of the water dissociation equilibrium:

$$2\,H_2O \rightleftharpoons H_3O^+ + OH^-$$

The rate at which protons and hydroxide ions are removed from the bipolar membrane, that is, the maximum electrical current, is limited by the rate of water diffusion into the bipolar membrane and the water dissociation rate. The water dissociation is given by:

$$J_{H^+} = J_{OH^-} = k_d\, C_{H_2O} 2\lambda \tag{3.94}$$

where J is the maximum ion flux from the bipolar membrane into the outer phases, k_d the water dissociation rate constant, C the concentration in the transition layer, and 2λ is the thickness of the transition layer.

Figure 17. Schematic illustrating the function of a bipolar membrane

The water dissociation rate constant k_d at 25°C is 2.5×10^{-5} s^{-1}. The water concentration in pure water is 55.5 mol L^{-1}. Assuming a thickness of the transition layer of 1 nm, the maximum ion fluxes J_{H^+} and J_{OH^-}, respectively, calculated by Equation (3.95), would be 1.4×10^{-9} mol m^{-2} s^{-1}. The electrical current density i is given by:

$$i = F\sum z_i J_i. \tag{3.95}$$

Thus, the ion fluxes J_{H^-} and J_{OH^-} would correspond to current density of about 1.4 × 10×4 A m^{-2}. In practice, however, bipolar membranes can be operated at current densities in excess of 1000 A m^{-2} [60]. This means that the simple model of a bipolar membrane is incorrect and that water dissociation is at least 10^6 times faster in bipolar membranes than in solution. The actual mechanism of water dissociation, which to a large extent determines the overall efficiency of the process, is still the subject of controversial discussion, and various models are suggested in the literature to explain the accelerated water dissociation which is observed in the practical application of bipolar membranes [61-63].

The energy required for the production of acids and bases in a bipolar membrane at constant temperature and pressure can be calculated from the concentration chain of solutions with different H^+ ion activities. The Gibbs free energy of water dissociation in a bipolar membrane can be calculated from the difference in the pH values of the solution in the phases between the cation- and anion-exchange layers of the bipolar membrane and the solutions outside the bipolar membrane and is given by:

$$\Delta G = RT \ln \frac{a^i_{H^+} a^i_{OH^-}}{a^o_{H^+} a^o_{OH^-}} = RT \ln \frac{K_w}{a^o_{H^+} a^o_{OH^-}} = 2.3RT\Delta pH = F\Delta\varphi \tag{3.96}$$

where ΔG is the Gibbs free energy, R the gas constant, T the absolute temperature, F the Faraday constant, a the activity of H^+ and OH^- ions, $\Delta\varphi$ the electrical potential difference between the solution in the bipolar membrane and the solutions outside the bipolar membrane, ΔpH the difference in pH value of the two solutions separated by the bipolar membrane, K_w the dissociation constant of water, and superscripts i and o refer to the interface between the cation- and anion-exchange layers of the bipolar membrane and the outside solutions, respectively.

At 25°C –log K_w is 13.997. The free energy for the dissociation of 1 mol of water, and thus for the production of 1 mol L^{-1} acid and base at 25 °C, is 79.887 kJ or 0.0222 kW·h. The voltage drop between the two outside solutions is 0.828 V. The actual potential drop across the bipolar membrane is higher due to the electrical resistance of the membranes and the solutions.

3.9. Energy Requirements of Membrane Processes

The energy required in membrane processes is the sum of two terms: 1) the energy to transfer the components from the feed mixture through a membrane into the permeate mixture, and 2) the energy required to pump the solutions through the membrane apparatus and to operate the process monitoring and control devices. The second term depends on the plant capacity and process design. The energy required for separating different components permeating through a membrane consists of two parts. The first part is the reversible energy given by the Gibbs free energy obtained when the retentate and permeate solutions are mixed. It is the minimum energy required for the separation of components in a mixture. It is identical for any separation process. The second part is the energy required to overcome the friction between the transported components and the membrane matrix. It represents the irreversible energy loss.

3.9.1. *Minimum Energy Required for Separation*

The minimum work that is required for the separation of various components from a mixture in a membrane process is given by the Gibbs free energy of mixing. which is given at constant pressure and temperature by:

$$(d\Delta G^m)_{p,T} = \Delta G' - \Delta G'' = \sum_i (\mu'_i \Delta n'_i - \mu''_i \Delta n''_i) \cong RT\sum_i \Delta n_i \ln \frac{a'_i}{a''_i} \tag{3.97}$$

where ΔG^m is the Gibbs free energy of mixing two solutions indicated by ′ and ″, μ the chemical potential, a the activity, n the number of moles, and subscript i refers to individual components.

For filtration processes such as reverse osmosis the energy requirement for removing the solvent from the solution can be expressed by the difference in the osmotic pressure of the two solutions, which for a strictly semipermeable membrane is given by:

$$\Delta\pi = \frac{RT}{V_w} \frac{\ln a'_w}{\ln a''_w} \tag{3.98}$$

where the subscript w refers to the solvent, for example, water.

Introducing Equation (3.98) into Equation (3.97) leads to:

$$\Delta G^m = \Delta n_w V_w \Delta\pi \cong V_f \Delta\pi \tag{3.99}$$

where $\Delta\pi$ is the osmotic pressure difference between the two solutions ′ and ″ separated by the membrane, and V_w and V_f are the partial molar volumes of the solvent and the filtrate, which for a dilute solution is to a first approximation given by $\Delta n V_w \cong V_f$.

In electrodialysis the change of the Gibbs free energy for converting a feed solution into a concentrate and a diluate is given by [56]:

$$\Delta G_{total} = \nu_d RT\left(n_s^c \ln \frac{C_s^c}{C_s^f} + n_s^d \ln \frac{C_s^d}{C_s^f}\right) \tag{3.100}$$

where ΔG_{total} refers to the Gibbs free energy change required for the production of the diluate, C the salt concentration, ν_d the stoichiometric dissociation coefficient, and superscripts f, c, and d refer to the feed, the concentrate, and the diluate.

3.9.2. *Practical Energy Requirements of Membrane Processes*

The minimum energy requirement for the separation of molecular mixtures such as salt solutions, discussed in Section Minimum Energy Required for Separation refers to an idealized, completely reversible process. In practice, such conditions never prevail and the energy requirements are usually significantly higher and rather different in different membrane separation processes. They are also a function of the membrane module construction and the overall process design. The practical energy requirements in the different processes are discussed in Section Practical Energy Requirements of Membrane Processes.

[Top of Page]

4. Membrane Separation Process Design and Operation

In the previous chapters the fundamentals of mass transport in membranes and the operating principle of various membrane separation processes are discussed. In this chapter the membrane separation processes are treated as unit operations and the various process designs and operation concepts are discussed.

4.1. Ultrafiltration, Microfiltration, and Reverse Osmosis

Microfiltration, ultrafiltration, and reverse osmosis have many chemical engineering aspects and process design features in common. In all three processes a hydrostatic pressure is utilized as driving force to transport certain components through a membrane which shows different permeability for different components. As a result a feed solution is converted into a filtrate and a retentate. The filtrate contains all components that have permeated the membrane, and the retentate contains the components that are retained or rejected by the membrane. The design of a microfiltration, ultrafiltration, or reverse osmosis process is illustrated in Figure 18.

Figure 18. Process scheme of ultrafiltration, microfiltration, and reverse osmosis

The performance of a membrane in a pressure-driven separation process is determined by its filtration rate, the membrane flux, and by the membrane separation properties. Membrane flux and separation properties are a function of membrane permeability for the different components of the solution and the applied hydrostatic pressure. But they are also determined by process and systems design.

4.1.1. *Recovery Rate, Membrane Rejection, Retentate and Filtrate Concentrations*

The separation capability of a membrane in reverse osmosis or ultra- and microfiltration can be expressed in terms of *membrane rejection* which describes the “true” rejection of a membrane. The true rejection of the membrane is given by:

$$R = \left(1 - \frac{C_i^f}{C_i^r}\right) \tag{4.1}$$

where R is the rejection of the membrane for a given component i at a defined hydrostatic pressure and feed solution concentration, and C_i^f and C_i^r are the concentrations of rejected components at a given point at the surface of the membrane facing the filtrate and at the surface facing the retentate, respectively. At a given temperature and pressure the rejection depends only on the membrane properties.

In many practical applications it is more convenient to express the rejection in reference to the feed solution:

$$R_0 = \left(1 - \frac{C_i^f}{C_i^o}\right) \tag{4.2}$$

where R_0 is the rejection in reference to the feed entering a filtration device and to the filtrate leaving the device after a certain amount of the feed has been recovered as filtrate.

Thus, the rejection in reference to the feed is a function of the recovery rate, which is given by the ratio of the filtrate to the feed volume.

$$\Delta = \frac{V^f}{V^o} \tag{4.3}$$

where Δ is the recovery rate and V^f and V^o are volumes of the filtrate and the feed solution.

Since in a practical application the concentration in the retentate is limited by factors such as osmotic pressure and viscosity, the solvent of the feed solution can not be completely recovered as filtrate. The recovery rate has a value between 0 and 1.

The concentrations in the retentate and the filtrate are not only determined by true membrane rejection *R*, but they are also a function of the recovery rate and of the operational parameters such as cocurrent or countercurrent flow of the concentrate and permeate solutions in the membrane device. For a simple batch-type filtration with complete mixing of the retentate and filtrate, as illustrated in Figure 19, the membrane flux is identical over the entire membrane area, and the relation between the concentration of retentate, filtrate, and feed solutions is given by a mass balance:

$$V^o C_i^o = V^r C_i^r + V^f C_i^f \tag{4.4}$$

where C_i^o, C_i^r, and C_i^f are the concentrations in the feed solution, in the retentate, and in the filtrate.

Figure 19. Schematic illustrating a batch filtration with complete mixing of filtrate and retentate

If concentration polarization effects are neglected the true membrane rejection can be calculated according to Equation (4.1) by assuming infinitesimal volume change, that is, the recovery rate approaches 0.

The concentration of a component in the retentate and filtrate at a given recovery rate is obtained from the mass balance by integration over the recovery rate:

$$C_i^r = C_i^o (1 - \Delta)^{-R} \tag{4.5}$$

The concentration in the filtrate is directly proportional to that in the retentate. Thus, for a given recovery rate, the filtrate concentration at any given time is found by introducing Equation (4.1) into Equation (4.5):

$$C_i^f = C_i^o (1 - R)(1 - \Delta)^{-R} \tag{4.6}$$

The filtrate concentration expressed in Equation (4.6) is the concentration corresponding to a given recovery rate, that is, during an infinitely small time interval. For most practical applications, however, the filtrate concentration obtained during an infinitely small time interval and at a certain recovery rate is of less interest than the *mixing cup concentration* [52], which is obtained when the entire filtrate up to a given recovery rate is collected and mixed. The mixing cup filtrate concentration $\overline{C}_i^f$ can be calculated by integration of Equation (4.5):

$$\overline{C}_i^f = \frac{C_i^o}{\Delta}\left[1 - (1 - \Delta)^{1-R}\right] \tag{4.7}$$

The mixing cup concentration is always lower than the concentration obtained during an infinitely short time period at a certain recovery rate. Figure 20 shows the retentate, filtrate, and mixing cup concentrations as a function of recovery rate for three different membrane rejection coefficients (*R* = 0.99, 0.9, 0.8, and 0.5).

Figure 20. Ratios of a) the retentate to feed solution concentration, b) the filtrate to feed solution concentration, and c) the mixing cup filtrate to feed solution concentration as a function of the recovery rate calculated for different membrane retentions

Figure 20 shows that the retentate concentration strongly depends on the recovery rate and reaches high values for membranes with high retention properties. The concentration in the filtrate also depends on the recovery rate and reaches high values for membranes with low retention properties. The mixing cup filtrate concentration increases less strongly with recovery rate, especially for membranes with high retention properties, and approaches its maximum value of 1 at a recovery rate of 1.

In membrane evaluation or characterization tests, the rejection *R* of a membrane can be calculated from two easily measurable values: the mixing cup filtrate concentration $\overline{C}_i^f$ and feed concentration C_i^o.

$$R = 1 - \frac{\ln\left(1 - \frac{\overline{C}_i^f \Delta}{C_i^o}\right)}{\ln(1 - \Delta)} \tag{4.8}$$

The significance of the mixing cup and maximum retentate concentrations can be illustrated in practical examples. For instance, in the production of potable water from seawater or brackish water, the concentration of total dissolved salts in the filtrates should not exceed 500 mg/L. This concentration is the mixing cup filtrate concentration. For given membrane and feed solution properties it is a function of the recovery rate and can be calculated by Equation (4.7).

If the feed solution contains a solute with limited solubility such as $CaSO_4$ or $CaCO_3$, the maximum recovery rate is determined by the maximum retentate concentration achievable without solute precipitation. The maximum recovery rate for given membrane and feed solution properties can be calculated by Equation (4.5).

4.1.2. *Solute Loss in Filtration*

In a membrane filtration process, the “product” may be either the filtrate, for example, as in the production of ultrapure water, or the retentate, for example, as in the concentration of proteins from whey. For membranes that are not strictly semipermeable some solute will permeate the membrane with the filtrate. This may affect the quality of the filtrate or lead to product losses.

The *fractional solute loss* δ of a component *i* is usually expressed by the amount of solute lost with the filtrate divided by the total amount of solute in the feed solution:

$$\delta = \frac{V^f \overline{C}_i^f}{V^o C_i^o} = 1 - (1 - \Delta)^{1-R} \tag{4.9}$$

where V^f and V^o are the volumes of the filtrate and the initial feed solution, $\overline{C}_i^f$ is the mixing cup filtrate concentration, C_i^o the initial feed solution concentration, Δ the recovery rate, and *R* the membrane rejection.

Product loss may be significant even with membranes that have a relatively high solute rejection when high retentate concentrations are desired, as illustrated in Figure 21.

Figure 21. Fractional solute loss in membrane filtration calculated as a function of the recovery rate for different membrane retentions

4.1.3. *Effect of Osmotic Pressure on the Filtration Rate*

The main difference between reverse osmosis and ultra- or microfiltration is the size or molecular mass of the solutes separated from a solution. In reverse osmosis, low molecular mass components are separated from a solvent. A solution of low molecular mass components can have a significant osmotic pressure that must be overcome by the hydrostatic pressure applied as driving force for the separation. The osmotic pressure is always negligibly low in microfiltration. In ultrafiltration of macromolecular solutions it may have an effect on the filtration rate. In reverse osmosis of low molecular components such as salts the osmotic pressure plays a very important role. It often is the limiting parameter for the maximum concentration that can be achieved in the retentate.

The osmotic phenomenon and the osmotic pressure of a solution is discussed in Section Osmotic Equilibrium, Osmotic Pressure, Osmosis, and Reverse Osmosis. The osmotic pressure of a solution is proportional to its solute concentration and given by:

$$\pi = RT \sum_i g_i C_i \tag{4.10}$$

where *R* is the gas constant, *T* the absolute temperature, and *g* the osmotic coefficient, which is a correction factor for the nonideal behavior of a solution, C_i the concentration of a component *i*, which in a dissociated salt refers to individual particles (i.e. cations and anions).

The membrane flux rate is determined by the effective pressure, which is given by the difference between applied pressure and osmotic pressure. Since the osmotic pressure increases with increasing solution concentration and thus with increasing recovery rate, the membrane flux decreases with increasing recovery rate. In microfiltration and to a large extent also in ultrafiltration the osmotic pressure is negligibly low compared to the applied pressure because of the high molecular weight of the retained components. Therefore, the filtration flux will be independent of the feed or retentate concentration. This, however, is not the case in reverse osmosis. Here, the osmotic pressure is significant for even modestly concentrated

solutions and increases with increasing recovery rate. In many applications of reverse osmosis the recovery rate is limited by the osmotic pressure.

4.1.4. *Process Operating Mode*

In the practical application of filtration processes three modes of operation are used (Figure 22).

Figure 22. Schematic illustrating different operation modes of filtration processes: a) batch process, b) continuous process, and c) feed-and-bleed process

In the batch process depicted in Figure 22a a given feed volume is placed in a pressure vessel. Under a hydrostatic pressure certain components, mainly solvents, permeate the membrane and are collected as filtrate. The components retained by the membrane are concentrated. When a certain concentration in the retentate is achieved the process is terminated.

In the continuous process depicted in Figure 22b the feed solution is continuously fed into the filtration device, which generally consists of a membrane-lined channel or tube. Under a hydrostatic pressure certain components permeate the membrane and are collected as filtrate, which leaves the device through an outlet port. The retained components are concentrated during passage through the device and leave at the end of the process as the retentate. Depending on the flow velocity of the feed solution, the geometry of the device, and the filtration rate a certain recovery rate is achieved. If the recovery rate achieved in one process pass is not satisfactory a higher recovery rate can be obtained by applying a so-called feed-and-bleed operating mode. In this case part of the retentate is recycled to the device inlet and mixed with the feed solution, as shown in Figure 22c. Depending on the retentate recycling ratio, different recovery rates can be achieved. If a component is not completely retained by the membrane its concentration is proportional to the retentate concentration and thus increases with increasing recovery rate. If the concentration of partly retained components in the filtrate exceeds the desired maximum value in the given process path length part of the filtrate may be recycled to the feed inlet. By adjusting the ratio of the filtrate recycled to the feed to the overall filtrate the concentration in the filtrate can be kept to a desired value.

4.1.5. *Diafiltration Operating Mode*

A variation of the ultrafiltration process, generally referred to as diafiltration [64], is often used when more complete separation of micro- and macrosolutes is required. Diafiltration is used, for instance, to remove salts from a mixture with proteins or other macromolecular components. In this application it competes directly with dialysis. The principle of diafiltration is illustrated in Figure 23.

Figure 23. Schematic illustrating the diafiltration operating mode

The diafiltration membrane should retain macromolecular components, but should be permeable to microsolutes. If filtrate removed from the cell is replaced by pure solvent, the low molecular mass constituents are gradually washed out of the feed mixture. If the volume of the original solution is kept constant, the concentration in the diafiltration vessel can be calculated as a function of the membrane retention and the volume of diafiltration rinse solution (i.e., the pure solvent replacing the filtrate volume) by a mass balance which is:

$$\frac{V_f C_i^f}{dt} = -V_o \frac{d\,C_i^r}{d\,t} \tag{4.11}$$

By introducing $V_f = V_w$ and $C_i^f = (1–R)C_i^r$ into Equation (4.11) and integrating over a certain time period the concentration in the diafiltration vessel can be expressed by:

$$C_i^{rt} = C_i^{ro} \exp -(1-R)\frac{V_w}{V_o} \tag{4.12}$$

where C_i^f and C_i^r are the concentrations of component *i* in the filtrate and in the diafiltration vessel, C_i^{rt} and C_i^{ro} the concentrations in the diafiltration vessel at time *t* and at the beginning of filtration, V_o is the volume of the diafiltration vessel, V_f and V_w are the volumes of the filtrate and the rinse solution added during time *t*, and *R* is the rejection of the membrane for the component under consideration.

Figure 24. a) Reduced retentate concentration in diafiltration as a function of the ratio of rinse water volume to diafiltration vessel volume calculated for various membrane retentions, and b) fractional product loss in diafiltration as a function of the rinse water volume calculated for different membrane retentions

If the component is completely retained by the membrane (i.e., R = 1), the concentration in the batch cell remains constant. If the membrane is completely permeable to the component (i.e., R = 0), the concentration in the reactor decreases according to the exponential function of Equation (4.12). The “rinse-out” effect in diafiltration is illustrated in Figure 24a, which shows the reduced concentration in the diafiltration process as a function of the ratio of the rinse water volume to diafiltration vessel volume calculated for different membrane rejections.

If the macromolecular constituents are only partially rejected by the membrane, a substantial loss of product occurs. If complete removal of the low molecular mass components without substantial loss of macromolecular material is desired, rejection of the membrane should be close to zero for the component low in molecular mass and close to one for the macromolecular material.

As in ultrafiltration, product losses may be significant, for example, if the membrane does not reject the macromolecules completely in desalting a macromolecular solution. The fractional product loss δ is then given by

$$\delta = \frac{V^{\mathrm{f}}\overline{C}_i^{\mathrm{f}}}{V^{\mathrm{o}}C_i^{\mathrm{o}}} = 1 - \exp - (1 - R)\frac{V_{\mathrm{w}}}{V_{\mathrm{o}}} \tag{4.13}$$

where V is the volume, R the membrane rejection, $\overline{C}_i^{\mathrm{f}}$ the mixing cup concentration, C the concentration, superscripts o and f refer to the initial feed solution and the filtrate, and subscripts o and w to the original volume of the feed and the volume of the wash solution.

In Figure 24b the fractional product loss is shown as a function of the ratio of wash solution volume V_w to feed solution volume V_o for membranes with different rejection characteristics. The concentration of a low molecular mass solute is reduced to less than 1 % of its original value by a wash solution volume five times that of the feed solution volume when the membrane passes the solute unhindered (i.e., R approaching 0), as shown in Figure 24. If the solute is partially rejected by the membrane, correspondingly more wash solution is required to reduce the concentration of the low molecular mass solute below a certain value. On the other hand, when the membrane rejects the macrosolute completely (i.e., R approaching 1) no product is lost, but partial rejection leads to significant product loss, as shown in Figure 24b.

4.2. Gas Separation

In gas separation, a feed stream enters a membrane device as indicated in Figure 25. Under the driving force of a hydrostatic pressure difference, some components permeate the membrane while others are retained, and a feed stream is split into a permeate and a retentate.

Figure 25. Schematic illustrating gas separation as a unit operation

The different flow streams illustrated in Figure 25 are related with each other by the mass balance:

$$Q^{\mathrm{f}}X_j^{\mathrm{f}} = Q^{\mathrm{p}}X_j^{\mathrm{p}} + Q^{\mathrm{r}}X_j^{\mathrm{r}} \tag{4.14}$$

where Q is the flow stream, X the molar fraction of the component j, superscripts f, p, and r refer to feed, permeate, and retentate, respectively, and subscript j refers to a component in the gas mixture.

If the membrane has a higher permeability for one of the components in the feed mixture than for others, this component is enriched in the permeate and depleted in the retentate. Gases can be separated in microporous and in homogeneous membranes. The selectivity of microporous membranes is generally rather low because of the Knudsen diffusion transport mechanism.

For a practical application of gas separation it is of interest:

- To what extent can a given gas mixture be depleted of a certain component?
- To what extent can a given component be enriched in the permeate?
- How much of the original feed stream can be recovered as permeate or retentate?
- Which hydrostatic pressure difference is needed to achieve the desired separation?
- How much membrane area is required for this operation?

There are three crucial parameters that determine the efficiency of a membrane separation process. These are the membrane selectivity $S_{i,k}$, the ratio of the feed to permeate pressure, and the stage cut. The selectivity is given by the membrane properties and can be expressed by:

$$S_{j,k} = \frac{P_j}{P_k} \tag{4.15}$$

The pressure ratio and the stage cut are operating-related parameter given by:

$$\Phi = \frac{p^{\mathrm{p}}}{p^{\mathrm{f}}} \tag{4.16}$$

and

$$\theta = \frac{Q^{\mathrm{p}}}{Q^{\mathrm{f}}} \tag{4.17}$$

where *S* and *P* are the membrane selectivity and the permeability, Φ and *p* the pressure ratio and the hydrostatic pressure, θ and *Q* the stage cut and the gas flow rate, and subscripts *j*, *k*, p, and f refer to the components *j* and *k*, the permeate, and the feed.

The membrane separation factor $\alpha_{j,k}$ and the membrane enrichment factor $\beta_{j,k}$ are related to the membrane selectivity and the pressure ratio by:

$$\alpha_{jk} = \frac{X_j^{\mathrm{p}} X_k^{\mathrm{f}}}{X_j^{\mathrm{f}} X_k^{\mathrm{p}}} = S_{j,k} \frac{X_j^{\mathrm{p}}\Phi - X_j^{\mathrm{f}} X_k^{\mathrm{f}}}{X_k^{\mathrm{p}}\Phi - X_k^{\mathrm{f}} X_j^{\mathrm{f}}} \tag{4.18}$$

and

$$\beta_j = \frac{X_j^{\mathrm{p}}}{X_j^{\mathrm{f}}} = \frac{\alpha_{j,k}}{1 + (\alpha_{j,k} - 1) X_j^{\mathrm{f}}} \tag{4.19}$$

where α is the separation factor, β the enrichment factor, *S* the membrane selectivity for a binary mixture, Φ the pressure ratio, *X* the molar fraction, subscripts *k* and *j* refer to two components, and superscripts f and p to the feed and the permeate.

The pressure ratio Φ has a value between 0 and 1. Thus, the maximum separation and enrichment is achieved when the pressure ratio approaches zero. The effect of the pressure ratio on the enrichment or the separation that can be achieved in a separation process depends also on the construction of the membrane module and the mode of operation, such as cocurrent or countercurrent or complete mixing of feed and permeate. This makes the calculation of the enrichment as a function of the pressure ratio rather complex and requires numerical solutions which are described in detail in the literature or provided by companies selling gas separation equipment [2, 65-67]. Only for very simple cases such as complete mixing of permeate and retentate or for a very low stage cut can the composition of the permeate be calculated to a first approximation by [68]:

$$X_j^{\mathrm{p}} = \frac{X_j^{\mathrm{f}}\Phi}{2} + \frac{1}{2} + \frac{\Phi}{2(S_{j,k} - 1)} - \left[\left(\frac{X_j^{\mathrm{f}}\Phi}{2} + \frac{1}{2} + \frac{\Phi}{2(S_{j,k} - 1)}\right)^2 - \frac{S_{j,k}\Phi X_j^{\mathrm{f}}}{(S_{j,k} - 1)}\right]^{0.5} \tag{4.20}$$

A practical application of gas separation is the enrichment of oxygen in air using a silicone rubber membrane which has a selectivity of 2. The molar fraction of oxygen in air is assumed to be 0.2 and the stage-cut is assumed to be 0. In Figure 26 the calculated enrichment factor β and the separation factor α are shown as a function of the pressure ratio.

Figure 26. a) The oxygen enrichment factor α and b) the separation factor β as a function of the pressure ratio for a membrane selectivity $S_{O2/N2}$ of 2 and a feed composition of X_{O2}/X_{N2} of 0.2/0.8

The example of oxygen enrichment in air illustrated in Figure 26 shows that the maximum separation and maximum enrichment can only be achieved when the ratio of permeate over feed approaches 0, that is, when either the feed pressure is infinitely high or the permeate pressure approaches 0 and when the stage cut is 0. The above example also shows that the maximum molar fraction in air that can be achieved in gas separation using a silicone rubber membrane is about 0.33 if the pressure ratio and the stage cut approach 0.

The flux through a membrane is proportional to the pressure difference between the feed and the permeate side, as indicated in Equation (3.56). This means that to obtain high fluxes the pressure difference between feed and permeate should be as high as possible, and to obtain high separation the pressure ratio between the permeate and the feed should be as low as possible.

In gas separation the achievable separation or enrichment of a component in the permeate or retentate depends not only on the membrane properties and the applied hydrostatic pressure ratio but also on the so-called stage cut, which corresponds to the recovery rate used in filtration processes and which is given by:

$$\theta = \frac{V^{\mathrm{p}}}{V^{\mathrm{f}}} \text{ or } \theta = \frac{Q^{\mathrm{p}}}{Q^{\mathrm{f}}} \tag{4.21}$$

if a continuous process as shown in Figure 22 is considered.

Here $\hat{\theta}$ is the stage cut, V and Q are the volume and the volume flux, respectively, and superscripts p and f refer to permeate and feed. The stage cut has a value between 0 and 1.

The molar fraction of a component in the feed, the permeate, and the retentate is related to the stage cut by the mass balance expressed in Equation (4.14). Introducing the stage cut in this equation leads to:

$$X_j^{\mathrm{f}} = \theta X_j^{\mathrm{p}} + (1-\theta) X_j^{\mathrm{r}} \tag{4.22}$$

where X_j is the mole fraction of component j and superscripts f, p, and r refer to feed, permeate, and retentate.

The permeate and retentate concentration as a function of the stage cut is illustrated in Figure 27 for the separation of oxygen and nitrogen. The calculation is based on a membrane selectivity $S_{O2/N2}$ of 2 and a feed composition X_{O2}/X_{N2} of 0.2/0.8. Furthermore, it is assumed that the pressure ratio of permeate and retentate pressure approaches 0 and the retentate and permeate are completely mixed. Under the above conditions the highest oxygen concentration that can be reached in the permeate is 0.33 when the stage cut approaches 0. The lowest oxygen concentration in the retentate of 0.11 is reached when the stage cut approaches 1.

Figure 27. a) The oxygen permeate and b) the oxygen retentate concentration as a function of the stage cut assuming complete mixing of permeate and retentate, for a membrane selectivity $S_{O2/N2}$ of 2, and a feed composition of X_{O2}/X_{N2} of 0.2/0.8

In practical applications gas separation systems are not operated with complete mixing of the permeate and retentate, and the calculation of the permeate and retentate concentrations becomes significantly more complicated and depends on the membrane module design and flow conditions of permeate and retentate. In gas separating modules three idealized flow patterns can be assumed (Fig. 28). The effect of the various flow patterns on the performance of a unit is rather significant. The determination of the required membrane area and separation characteristics for the different flow patterns for binary and multicomponent mixtures are described in the literature, and computer programs for parametric studies are available for all flow patterns [65-67].

Figure 28. Schematic illustrating three idealized feed and permeate flow patterns used in gas separation systems. a) Complete mixing of feed and permeate; b) Countercurrent plug flow of feed and permeate; c) Cocurrent plug flow of feed and permeate

The separation obtained in a single permeation stage can be multiplied many times, if necessary, by connecting an appropriate number of stages in series to form a countercurrent *permeation cascade*. There are two possible arrangements. In the first arrangement there is no reflux of the retentate. A typical section of a permeation cascade without reflux of the retentate is shown in Figure 29a. In this simple arrangement the permeate from stage n becomes the feed for the next higher stage $n + 1$, and the retentate is disposed of. In the second case the retentate is refluxed, that is, the retentate of stage n is mixed with the next lower stage n–1 and so on. All permeate streams must be recompressed before entering a higher stage. The simple cascade without reflux of the retentate is only of use when the retentate is virtually of no value and large enrichment factors or product concentrations in the permeate are required. If a cascade with reflux of the retentate is used there are two sections depending on the position where the original feed solution is introduced into the cascade. One is the so-called enrichment section where the product is enriched in the permeate, and the other is the stripping section where the product is enriched in the retentate. The principle of a permeation cascade with reflux of the retentate is illustrated in Figure 29b.

Figure 29. Flow diagram of permeation cascades a) without reflux of the retentate and b) with reflux of the retentate

The number of stages needed for a required separation factor can be determined by the McCabe – Thiele method, a graphical procedure commonly used in the design of distillation columns. The subject of cascade operation is of rather fundamental importance for all separation processes and therefore treated in detail in the corresponding literature [69].

The graphical procedure of determining the number of stages is based on two basic relations. One is the equilibrium curve expressing the relation between the composition of the permeate and the retentate in one stage; this is a function of the membrane properties, operating pressures, stage cut, and flow pattern. The second curve is the operating line, which describes the relation between the composition of the permeate leaving stage *n* and that of the retentate of the next higher stage. The operating line depends on the operating scheme used in a cascade (e.g., variable or constant stage cut) and is the material balance between two stages. The application of the countercurrent flow principle in a reflux cascade has led to the development of the membrane column [70]. In analogy to distillation a membrane column can be regarded as a reflux cascade with an infinite number of stages, and like a reflux cascade the membrane column will produce an enriched retentate in the stripping section and an enriched permeate in the enrichment section. Compared to the normal cascade the membrane column has the advantage of being able to produce highly enriched products both in the permeate and retentate without pressurizing the permeate before it enters the next stage of the cascade, and it thus requires less energy for compression of the gas. On the other hand, the membrane column requires a significantly higher membrane surface area. Whether a column or a cascade is optimal for a given separation problem must be decided by an economic analysis. It is highly dependent on membrane properties and module design. Although the membrane-column concept can in principle be applied to other membrane separation processes such as reverse osmosis, it is most important for gas separation.

4.3. Pervaporation

In pervaporation, volatile organic components are removed from a liquid feed mixture through a semipermeable membrane into a gas phase. The separation of components from a liquid mixture is determined not only by differences in their vapor pressures, as is the case in distillation, but also by their permeation rates through the membrane. As in gas separation the driving force for the transport is the chemical potential gradient of the permeating components in the membrane, which can be related to the partial vapor pressures in the liquid and vapor phase. In gas separation, the chemical potential difference is induced by a hydrostatic pressure difference. In pervaporation, however, the chemical potential gradient is usually induced by applying a vacuum on the permeate side of a membrane, or by applying a temperature difference between the liquid feed mixture and the permeate gas phase. A sweeping gas can also be used to remove the permeating component. The mass transport in a pervaporation membrane can be described by the same mathematical relations as the gas transport with the exception that the chemical potential in the membrane on the feed side of the membrane is expressed by the molar fraction and the activity coefficient in the liquid phase as discussed in Section Gas Separation.

The different modes of operation in pervaporation are illustrated in Figure 30.

Figure 30. Schematic illustrating different operation modes used in pervaporation: a) vacuum-driven pervaporation, b) temperature-difference-driven pervaporation, and c) sweeping-gas-driven pervaporation

4.4. Dialysis

Dialysis was one of the first technically used membrane separation processes and today is still among the most important commercially. A large fraction of today's artificial kidneys are dialyzers, and hemodialysis is the largest single application of a membrane separation process.

In a dialyzer, one or more solutes are transferred from the feed solution to the dialysate or stripping solution through a membrane under the driving force of a concentration gradient. The principle of the process has been discussed earlier. The mass transfer in a dialyzer is illustrated in Figure 31. A dialyzer cell contains two chambers separated by a membrane. A feed solution to be depleted of a solute is pumped through one chamber while the receiving fluid (dialysate) is passed through the other chamber. The three most common modes of operating a dialyzer are parallel flow and countercurrent flow of feed solution and dialysate and feed flow with the dialysate completely mixed.

Figure 31. Operating scheme of a dialyzer (*Q* and *C* refer to volume flow rate and concentration of the component to be removed, subscripts f and d to feed solution and dialysate, and superscripts in and out to inlet and outlet)

The overall efficiency of a dialyzer is governed by two interdependent factors: the ratio of the flow rates of the two fluids and the rate constant for solute transport between the fluids, which is determined by membrane properties, membrane area, fluid channel geometry, and local fluid velocities. A material balance can be expressed by:

$$N_i = Q_f\left(C_i^{f\,-\mathrm{out}}\,C_i^{f}\right) = Q_d\left(C_i^{d\,-\mathrm{in}}\,C_i^{d}\right) \tag{4.23}$$

where *N* is the overall transport rate of the solute, *Q* and *C* are the volume flow rate and the concentration, subscripts *i*, f, and d refer to a component, the feed solution, and the dialysate, and superscripts f and d, and in and out refer to feed and dialysate, and inlet and outlet. The overall rate of solute transport is also expressed by:

$$N_i = J_i A = k^* A \Delta \overline{C}_i \tag{4.24}$$

where J_i is flux rate and $\Delta \overline{C}_i$ the average concentration difference of component *i* between the fluids, *A* the membrane area, and *k** the overall rate constant. The efficiency of a dialyzer is expressed in terms of its *dialysance* D_f, which is defined as [71]:

$$D_f = \frac{N}{C_i^f - {}^{in}C_i^d} = \frac{k^* A \Delta \overline{C}_i}{C_i^f - {}^{in}C_i^d} \tag{4.25}$$

The dimensionless ratio D_f/Q_f is a convenient efficiency parameter, because it represents the fraction of maximum attainable solute depletion actually achieved in the feed.

The proper average solute concentration difference is the logarithmic mean of the inlet and outlet differences. The mean concentration difference between the feed and dialysate solution depends on the membrane module design and the mode of operation, that is, complete mixing of feed and dialysate or co- or countercurrent flow. The calculation of the dialysance for the different operation modes by simultaneous solution of Equations (4.23) to (4.25) using the logarithmic mean concentration difference as driving force is described in the literature [71].

In dialysis with cation- or anion-exchange membranes, which is used to recover acids or bases from a mixture with salts, the recovery rate of the acid or base and the maximum concentration that can be achieved is of interest. The recovery rate is given by:

$$\Delta = \frac{{}^{out}C_i^d Q^d}{{}^{in}C_i^f \; Q^f} \tag{4.26}$$

where Δ is the recovery rate of the desired product (acid or base), *C* the concentration, *Q* the volume flow through the dialysis cell, and superscripts f and d, and in and out refer to feed and dialysate, and inlet and outlet.

The recovery rate Δ determines how much of the acid or base which is in a mixture with a salt can be recovered. Δ has a value between 0 and 1. It is related to the concentration of the recovered product and the concentration in the depleted solution at the cell exit by:

$${}^{out}C_i^d = \frac{Q_f}{Q_d} \Delta \, {}^{in}C_i^f \tag{4.27}$$

and

$${}^{out}C_i^f = (1 - \Delta) {}^{in}C_i^f \tag{4.28}$$

According to Equations (4.23) to (4.28) the concentration of a component such as an acid or base in the final dialysate or the depleted feed solution can be determined as a function of the overall mass transfer coefficient, the total membrane area, and the volume flow rates of the feed and the product for different dialysis operations modes [72].

The modeling of diffusion dialysis only on the basis of concentration differences, as suggested in the literature [72], does not consider electrochemical interactions of the different ions (i.e. a diffusion potential or osmotic and electroosmotic effects) and can therefore only be considered as a first approximation for the design of a diffusion dialysis process.

4.5. Electrodialysis

The basic concept of electrodialysis is discussed in Section Principle of Electrodialysis. Although there are many different components necessary for the proper operation of an electrodialysis plant such as the electrical power supply, pumps, and control and monitoring devices, the stack is a key component in an electrodialysis unit. For designing and operating an electrodialysis stack certain process parameters must be taken into account and be controlled such as the feed solution concentration and the desired product and brine concentrations. Various modes of operation are possible such as batch or continuous. In many cases the desired desalination or concentration of a feed solution cannot be obtained in a single pass through the electrodialysis cells. To achieve a higher degree of desalination or concentration two or more stacks are placed in series. When high product recovery rates are required part of the brine may be recycled. A cell arrangement of an electrodialysis stack is shown schematically in Figure 32.

Figure 32. Schematic illustrating the construction of a sheet-flow electrodialysis stack

An electrodialysis stack is composed of a multitude of cells placed in parallel between two electrodes. The different cells are separated by ion-exchange membranes. In alternating cells a feed solution is concentrated and desalinated, respectively. A spacer-gasket arrangement separates the membranes and contains the manifolds to distribute the process fluids in the different compartments. In designing and operating an electrodialysis stack, several criteria concerning the hydrodynamic and electrical properties must be considered. A proper electrodialysis stack design should provide a maximum effective membrane area per unit stack volume and ensure equal and uniform flow distribution in each compartment. Any leakage between the diluate, concentrate, and the electrode cells should be prevented. The spacer screen should provide maximum mixing of the solutions at the membrane surfaces and should cause a minimum in pressure loss [73, 74]. In practice, two

different stack types are used on a large scale: sheet-flow and the tortuous path flow stacks. In a sheet-flow electrodialysis stack the solution flows in a straight path from the entrance to the exit ports, which are located on opposite sides of the gasket, as indicated in Figure 33a.

In the tortuous path flow stack, the membrane spacer gaskets have a long serpentine cutout which defines a long narrow channel for the fluid path and provides higher residence times of the solution in the cells even at high flow velocities. A tortuous path flow spacer gasket is shown schematically in Figure 33b.

Figure 33. Concept of a) a sheet-flow and b) a tortuous path flow electrodialysis spacer gasket

The distance between the membrane sheets (cell thickness) should be as small as possible to minimize energy consumption due to electrical resistance of the solutions. In industrial-size electrodialysis stacks, membrane distances are typically between 0.3 and 2 mm. A spacer is introduced between the individual membrane sheets to support the membrane and to control the solution flow distribution.

Solution flow velocities in sheet-flow stacks are typically 3 – 10 cm s^{-1}, whereas in tortuous path flow stacks the solution flow velocities are 15 to 50 cm s^{-1}. Because of higher flow velocities and longer flow paths, higher pressure drops on the order of 2 – 3 bar are obtained in stacks with tortuous path flow spacers compared to sheet-flow systems, which have pressure drops between 0.5 and 2 bar. In a practical electrodialysis system, 200 to 1000 cation- and anion-exchange membranes are installed in parallel to form an electrodialysis stack providing 100 to 500 cell pairs. At each end of a stack is an end-plate that contains the electrodes. Depending on the feed solution composition and the product requirements electrodialysis units can be operated in batch-type, continuous, or feed-and-bleed mode with partial recycle of the diluate and concentrate streams.

In practical applications two basic concepts of electrodialysis are used. One is referred to as unidirectional electrodialysis [75] and the other as electrodialysis reversal [76]. In a unidirectionally operated electrodialysis stack the electrical potential gradient across the stack is permanently applied in one direction, and the diluate and concentrate cells are also permanently fixed over the period of operation. Unidirectionally operated electrodialysis plants are rather sensitive to membrane fouling and scaling and often require frequent stack-cleaning procedures. In electrodialysis reversal the change of the electric potential across the stack is accompanied with a reversal of the flow streams, so that the diluate becomes the concentrate and vice versa. In practical applications the polarity is changed at time intervals ranging from a few minutes to several hours. The advantage of electrodialysis reversal is that precipitates in the brine cells are redissolved when the polarity is reversed and the brine cell becomes the diluate cell. During the reversal of the polarity and the flow streams there is a brief period when the concentration of the desalted product exceeds the product quality specification and must be discharged. Thus, in electrodialysis reversal a certain amount of the product is always lost to the waste stream. This is generally no problem in desalination of brackish water, but it may be not acceptable in certain applications in the food and drug industry when feed solutions with high-value products are processed.

The main advantage of electrodialysis reversal is that suspended matter, polyelectrolytes, and multivalent salts that are precipitated on the membrane surfaces are removed when the polarity and the flow streams are reversed. This is illustrated in Figure 34, which shows a typical electrodialysis cell formed by a cation- and anion-exchange membrane between two electrodes. If an electric field is applied to a feed solution containing negatively charged particles or large organic anions these components will migrate to the anion-exchange membrane and be deposited on its surface. If the polarity is reversed the negatively charged components will migrate away from the anion-exchange membrane back into the feed stream and the membrane properties are restored. This procedure is very effective and is used today in almost all electrodialysis water desalination systems.

Figure 34. Schematic illustrating the removal of deposited negatively charged colloidal components from the surface of an anion-exchange membrane by reversing the electric field

The degree of desalination that can be achieved in passing the feed solution through a stack is a function of the solution concentration, the applied current density, and the residence time of the solution in the stack, which is determined by the process path length. If the required product concentrations are not achieved in a single process path, electrodialysis can be operated as a multistage process or as a process with feed and bleed in which the diluate or the concentrate or both are partially recycled. Staging can be done by complete physical separation of the stacks, with each having its own set of electrodes, pumps, and power supply, or by internal staging where one set of electrodes and pumps is needed. A disadvantage of simple staging is a constant recovery rate of the feed solution. If variable recovery rates are desired the system must be operated in a feed-and-bleed mode. In this operating mode both the brine and the product concentration can be controlled independently.

4.5.1. *Mass Transport in an Electrodialysis Stack*

The degree of desalination in electrodialysis can be expressed by a material balance between the feed, the concentrate, and the diluate solutions. It is a function of the residence time of the different solutions in the cells, that is, the flow velocities of the solutions, the membrane area in a cell pair, and the applied current density. Calculation of the complete mass balance between the diluate and concentrate flow stream can be rather complex for multicomponent solutions and high ion

concentrations, which means high osmotic pressures and activity coefficients that deviate largely from 1 and when the two flow streams have different flow velocities and directions. However, in many electrodialysis applications the concentrate and diluate cells have identical geometries and flow conditions, that is, the flow in both cells is cocurrent and of identical velocity. The transfer of ions in such a cell arrangement is illustrated in Figure 35.

Figure 35. Schematic illustrating the flow of diluate and concentrate streams parallel to the membrane surface in a cell pair of an electrodialysis stack and the concentration change between diluate and concentrate solution ΔC_s due to the ion flux through the membrane

The figure shows a cell pair of an electrodialysis stack with diluate and concentrate flow streams parallel to the membrane surface in the *x* direction. The geometry of both cells are identical and the two flow streams have the same flow velocity. It is assumed that the concentration potential between the two flow streams due to different concentrations in the diluate and concentrate solutions is negligibly low compared with voltage drops due to the resistance of the solutions, and that changes in the resistance of the solutions due to the boundary layer effects are also negligible. Finally, it is assumed that all diffusion processes between the two flow streams can be neglected and the only driving force for the transport is the electrical potential gradient, which is constant over the entire cell length.

Under the above-stated assumptions the degree of desalination of a given feed solution, that is, the changes in the ion concentration in the diluate and concentrate cells in an area element expressed in equivalents, can be calculated as a function of the solution properties, the applied voltage, and the stack design by:

$$\mathrm{d}\,C_s^{\mathrm{d}} = -\mathrm{d}\,C_s^{\mathrm{c}} = \mathrm{d}^{\Delta}C_s = J_s \tag{4.29}$$

Furthermore:

$$J_s = \frac{i\xi}{FQ_{\mathrm{cell}}}\mathrm{d}A_{\mathrm{cell}}, \mathrm{d}A_{\mathrm{cell}} = Y\mathrm{d}x, \quad \text{and} \quad i = \frac{U_{\mathrm{cell}}}{\frac{\Delta\left(C_s^{\mathrm{c}}+C_s^{\mathrm{d}}\right)}{\Lambda_s C_s^{\mathrm{c}} C_s^{\mathrm{d}}} + r^{\mathrm{am}} + r^{\mathrm{cm}}} \tag{4.30}$$

where *i* is the current density, *F* the Faraday constant, ξ the current utilization, U_{cell} the applied voltage across the cell pair, $\mathrm{d}A_{\mathrm{cell}}$ a cell pair area element, Δ the thickness of the cell, Λ_s the equivalent conductivity of the solution (average value for the concentration range considered), r^{am} and r^{cm} are the resistances of the anion- and cation-exchange membranes, and $\mathrm{d}C_s^{\mathrm{d}}$ and $\mathrm{d}C_s^{\mathrm{c}}$ the concentration changes in a volume element of the diluate and concentrate cell, $\mathrm{d}^{\Delta}C_s$ is the concentration change in a volume element of the diluate and concentrate cell due to the ion flux through the membrane, Q_{cell} the flow stream in the diluate or concentrate cell, *Y* the cell width, and d*x* a distance change in direction of the flow stream parallel to the membrane surface.

Introducing Equation (4.29) into Equation (4.30) and integrating over the cell length leads to:

$$\ln\frac{C_s^{\mathrm{c}}C_s^{\mathrm{fd}}}{C_s^{\mathrm{d}}C_s^{\mathrm{fc}}} + \frac{\Lambda_s(r^{\mathrm{am}}+r^{\mathrm{cm}})\left(C_s^{\mathrm{fd}}-C_s^{\mathrm{d}}\right)}{\Delta} = \frac{\Lambda_s\xi U_{\mathrm{cell}}YX}{FQ_{\mathrm{cell}}\Delta} \tag{4.31}$$

where $C_s^{\mathrm{fd}}$and C_s^{fc} are the concentrations of the diluate and the concentrate at the cell inlet, and C_s^{d} and C_s^{c} the concentrations of the diluate and the concentrate at the cell outlet.

The total flow of the diluate or concentrate solution through a stack is given by:

$$Q_{\mathrm{st}} = N\,Q_{\mathrm{cell}} = N\Delta Yu \tag{4.32}$$

where Q_{st} is the total solution flow of the diluate or the concentrate through the entire stack, Q_{cell} the flow through one cell, *N* the number of cells in the stack, Δ the thickness and *Y* the width of a cell, and *u* is the linear flow velocity in the cell.

The total voltage across the stack U_{st} is given by:

$$U_{\mathrm{st}} = NU_{\mathrm{cell}} \tag{4.33}$$

Equations (4.31) to (4.33) give the relations between the various stack construction data such as cell length, cell width, and cell thickness, the solution properties such as the concentrations and conductivities of the feed, the concentrate, and the product, the flow velocity in the cells, and the applied voltage. However, to design an electrodialysis stack for a certain plant capacity on the basis of Equation (4.33) it must be taken into consideration that the current density cannot exceed a certain value, which is referred to as limiting current density. Since the applied voltage is related to the current density it should not exceed a certain value.

The current density and thus the voltage that can be applied in a practical electrodialysis, however, is limited due to concentration polarization and ion depletion at the membrane surfaces in the diluate cell. The causes and consequences of the limiting current density are discussed in more detail below.

Introducing the limiting current density into Equation (4.30) and multiplying by the number of cell pairs in the stack gives the limiting applied voltage across the stack $U_{st,lim}$:

$$U_{st,lim} = i_{lim}\frac{N\Delta}{\Lambda_s}\left[\frac{C_s^d}{C_s^c} + 1 + \frac{\Lambda_s C_s^d}{\Delta}(r^{am} + r^{cm})\right] \tag{4.34}$$

where i_{lim} is the limiting current density, C_s^d and C_s^c are the concentrations in the diluate and concentrate solutions, Λ_s is the equivalent conductivity of the salt solution, r^{am} and r^{cm} are the area resistances of the anion- and cation-exchange membranes, Δ is the cell thickness, and $\Re$ the number of cell pairs in the stack.

Combination of Equations (4.31), (4.33), and (4.34) and rearranging gives the required membrane area of the complete stack as function of the cell geometry, the applied voltage, the concentrations of the feed, concentrate, and diluate solutions, and the solution flow velocities:

$$A_{st} = N_{cell}\frac{\left[\ln\frac{C_s^c C_s^{fd}}{C_s^d C_s^{fc}} + \frac{\Lambda_s(r^{am}+r^{cm})\left(C_s^{fd}-C_s^d\right)}{\Delta}\right]}{\left[\frac{C_s^d}{C_s^c} + 1 + \frac{\Lambda_s C_s^d}{\Delta}(r^{am} + r^{cm})\right]}\frac{Yu\Delta u\Delta_s^d}{\xi\, i_{lim}} \tag{4.35}$$

where A_{st} is the total cell pair area installed in the stack, N_{cell} the number of cell pairs in the stack, C_s^{fd} and C_s^{fc} are the concentrations of the diluate and the concentrate at the cell inlet, C_s^d and C_s^c are the concentrations of the diluate and the concentrate at the cell outlet, Λ_s is the equivalent conductivity of the salt solution, r^{am} and r^{cm} are the area resistances of the anion- and cation-exchange membranes, Δ is the cell thickness, i.e., the distance between the cation- and anion-exchange membrane, Y the cell width, u the linear flow velocity, F the Faraday constant, i_{lim} the limiting current density, and ξ the current utilization.

From the cell pair area required for a certain plant capacity and the cell dimensions the process path length L_{pp} can be determined by:

$$L_{pp} = \frac{A_{cell}}{Y} \tag{4.36}$$

It becomes equal to the cell length X when desalination is achieved in one pass through the cell.

4.5.2. *Energy Requirements in an Electrodialysis Desalination Process*

The total energy requirements in a practical electrodialysis process is the sum of four terms:

- The energy required for the transport of ions from a feed to a concentrate solution.
- The energy necessary to pump the solutions through the stack from a feed solution reservoir to the product tank and brine disposal.
- The energy consumed by the electrode reactions.
- The energy required to operate various process control and measuring instruments.

The last two terms can generally be neglected in larger capacity plants. However, they can be significant in specific applications of small-capacity plants used in the chemical industry or in the treatment of certain wastewater streams.

The required electrical power for the transfer of ions in a desalination process is given by the total current passing through the stack multiplied by the applied voltage. The total current passing through a cell pair is given by:

$$I = \frac{N_{cell}Q_{cell}F\left(C_s^{fd} - C_s^d\right)}{\xi} \tag{4.37}$$

where I is the total electric current passing through the cell pair, Q_{cell} the flow rate of the solution in the diluate cell, C_s^{fd} and C_s^d are the diluate feed and product equivalent concentrations, and N_{cell} is the number of cell pairs in the stack.

The electric power P_{des} required for the desalination process in a stack is given by:

$$P_{des} = N_{cell}U_{cell}I = \frac{FQ_{cell}\left(C_s^{fd} - C_s^d\right)}{\xi}N_{cell}U_{cell} \tag{4.38}$$

Introducing Equations (4.30) and (4.31) into (4.38) and rearranging gives the power requirement for the desalination process in a cell pair:

$$P_{des} = N_{cell}U_{cell}I = \frac{N_{cell}}{A_{cell}}\left[\frac{\Delta\ln\frac{C_s^{fd}C_s^c}{C_s^{fc}C_s^d}}{\Lambda_s\left(C_s^{fd} - C_s^d\right)} + r^{am} + r^{cm}\right]\left[\frac{Q_{cell}^d F\left(C_s^{fd} - C_s^d\right)}{\xi}\right]^2 \tag{4.39}$$

Multiplying the power requirements for one cell pair with the time of operation and the number of cell pairs in the stack gives the energy required for the amount of product obtained in this time:

$$E_{\mathrm{des}} = N_{\mathrm{cell}} U_{\mathrm{cell}} I t = \frac{N_{\mathrm{cell}} t}{A_{\mathrm{cell}}} \left[\frac{\Delta \ln \frac{C_{\mathrm{s}}^{\mathrm{fd}} C_{\mathrm{s}}^{\mathrm{c}}}{C_{\mathrm{s}}^{\mathrm{fc}} C_{\mathrm{s}}^{\mathrm{d}}}}{\Lambda_{\mathrm{s}} \left(C_{\mathrm{s}}^{\mathrm{fd}} - C_{\mathrm{s}}^{\mathrm{d}} \right)} + r^{\mathrm{am}} + r^{\mathrm{cm}} \right] \left[\frac{Q_{cell}^{d} F \left(C_{\mathrm{s}}^{\mathrm{fd}} - C_{\mathrm{s}}^{\mathrm{d}} \right)}{\xi} \right]^2 \tag{4.40}$$

Thus, the specific energy required for a unit volume of product is:

$$E_{\mathrm{des/spce}} = \frac{N_{\mathrm{cell}} U_{\mathrm{cell}} I}{Q_{\mathrm{st}}} = \frac{N_{\mathrm{cell}}}{A_{\mathrm{cell}} Q_{\mathrm{st}}} \left[\frac{\Delta \ln \frac{C_{\mathrm{s}}^{\mathrm{fd}} C_{\mathrm{s}}^{\mathrm{c}}}{C_{\mathrm{s}}^{\mathrm{fc}} C_{\mathrm{s}}^{\mathrm{d}}}}{\Lambda_{\mathrm{s}} \left(C_{\mathrm{s}}^{\mathrm{fd}} - C_{\mathrm{s}}^{\mathrm{d}} \right)} + r^{\mathrm{am}} + r^{\mathrm{cm}} \right] \left[\frac{Q_{\mathrm{cell}}^{\mathrm{d}} F \left(C_{\mathrm{s}}^{\mathrm{fd}} - C_{\mathrm{s}}^{\mathrm{d}} \right)}{\xi} \right]^2 \tag{4.41}$$

where E_{des} and $E_{des/spec}$ are the desalination costs for electrodialysis and the cost per unit volume of product, I is the total current and U_{cell} the voltage per cell, N_{cell} the number of cell pairs in a stack, t the time of operation, C_s^{fd} and C_s^{fc} are the equivalent concentrations of the diluate and the concentrate at the cell inlet, C_s^{d} and C_s^{c} the concentrations of the diluate and the concentrate at the cell outlet, Λ_s is the equivalent conductivity of the salt solution, r^{am} and r^{cm} are the area resistances of the anion- and cation-exchange membranes, Δ is the cell thickness, ζ the current utilization, Q_{cell} and Q_{st} are the diluate flow velocities in a cell and in the entire stack, respectively, and A_{cell} is the cell pair area.

The energy needed to pump the various flow streams through the stack is given by:

$$E_{\mathrm{p/spce}} = \frac{E_{\mathrm{p}}}{Q^{\mathrm{d}} t} = k_{\mathrm{eff}} \frac{\left(Q^{\mathrm{d}} \Delta p^{\mathrm{d}} + Q^{\mathrm{c}} \Delta p^{\mathrm{c}} + Q^{\mathrm{e}} \Delta p^{\mathrm{e}} \right)}{Q^{\mathrm{d}}} \tag{4.42}$$

where $E_{p/spec}$ is the total energy per unit diluate water for pumping the diluate, the concentrate, and the electrode rinse solution through the stack, k_{eff} an efficiency term for the pumps, and Q^d, Q^c, and Q^e are the volume flow rates of the diluate, the concentrate, and the electrode rinse solution through the stack.

The energy consumed by the electrode reaction and required for the operation of the control and measuring instruments is generally neglected or taken as a fixed item which is between 1 and 3 % of the energy used for ion transfer and pumping of the solutions.

4.5.3. *Electrodialysis Process Costs*

The total production costs in electrodialysis are the sum of fixed charges associated with amortization of the plant investment costs and of operating costs such as energy and maintenance requirements. The investment costs include nondepreciable items such as land and depreciable items such as the electrodialysis stacks, pumps, electrical equipment, monitoring and control devices, and membranes. The required membrane area for a given plant capacity is inversely proportional to the current density and directly proportional to the quantity and quality of the product from a given feed solution.

The total operating costs of the electrodialysis plant include energy and maintenance costs and all pre- and post-treatment procedures. They are also a function of the membrane properties, feed and product composition, and several process and equipment design parameters such as stack construction. A dominant role in electrodialysis process costs is played by the applied current density, since it directly affects the investment and energy costs. The required membrane area decreases with increasing current density, while the consumed energy increases with increasing current density, as shown by Equations (4.35) and (4.41). Thus, the total product costs, which are the sum of energy costs, amortization, and maintenance costs, are a function of the current density and will reach a minimum at a certain current density. This is schematically shown in Figure 36.

Figure 36. Schematic illustrating the process costs in electrodialysis as a function of the applied current density

Here the total process costs, the energy costs, the amortization on membrane and hardware investment, and the maintenance costs are shown as function of the applied current density. The optimum operating current density in electrodialysis depends to a large extent on the equipment, especially the membrane cost and life, and on the cost of energy. The current density to be applied in electrodialysis is determined by the limiting current density, which should not be exceeded because of possible pH changes in the diluate and concentrate. However, in certain cases it is possible to operate well above the limiting current density [77].

In many applications, electrodialysis competes with other separation processes. Although the theoretically required minimum energy is identical in all processes, the irreversible energy dissipation differs considerably. The desalination of a saline solution by, for example, reverse osmosis involves the passage of water through a membrane under the driving force of a hydrostatic pressure difference, whereas in electrodialysis the salt passes through a membrane under the driving force of an electrical potential difference. The irreversible energy loss in reverse osmosis is caused by hydraulic resistance of the membrane to the water flux and is thus independent of the feed salt concentration. In electrodialysis the irreversible energy loss is proportional to the number of ions transferred from a feed to a concentrate solution, and thus for a given product water concentration it is directly proportional to the feed water concentration. For feed solutions with low salt concentrations the

energy requirements are therefore generally lower for electrodialysis than for reverse osmosis; with feed solutions having a high salt concentration the situation is reversed.

Comparison of energy consumption in mass separation processes must consider the fact that in electrodialysis energy is required in the form of electricity, a relatively expensive form, whereas processes such as distillation use heat, a relatively inexpensive form.

4.6. Bipolar Membrane Electrodialysis Process Design

The basic concept of electrodialytic water dissociation with bipolar membranes is discussed in Section Electrodialysis With Bipolar Membranes. The main application of this process is the production of an acid and a base from the corresponding salt in a cell arrangement consisting of cation- and/or anion-exchange membranes and bipolar membranes in alternating series between two electrodes forming an array of individual cells. A repeating unit may be composed of a three-cell arrangement (Fig. 37a) or a two-cell arrangement (Fig. 37b and c) [78]. In the three-compartment cell design one cation-exchange, one anion-exchange, and one bipolar membrane with three flow streams in between them (i.e., the salt solution, the acid, and the base) represent a cell unit. In the two-compartment cell design a cation-exchange and a bipolar membrane, or an anion-exchange membrane and a bipolar membrane with two flow streams in between are arranged in parallel. One of the flow streams contains the salt solution in a mixture with the produced acid or base. In a three-cell arrangement relatively pure acids and bases are obtained. However, an additional monopolar membrane is needed which will increase the investment cost. The two-cell arrangement results in an acid or a base in a mixture with the salt. The two-cell arrangement is often applied when the product has a relatively low conductivity. This is, for instance, the case when certain organic acids which have a low degree of dissociation such as lactic acid are recovered from a fermentation broth. Without additional salt the poor conductivity in the acid compartment would result in excessive power consumption.

Figure 37. Schematic illustrating the cell arrangement in an electrodialytic water dissociation stack

a) A three-cell unit composed of an anion-exchange, a cation-exchange, and a bipolar membrane; b) A two-cell unit composed of a cation-exchange and a bipolar membrane; c) A two-cell unit composed of an anion-exchange and a bipolar membrane

As in conventional electrodialysis various modes of operation are possible such as batch, feed-and-bleed, and continuous processes [79].

The stack design used in electrodialysis with bipolar membranes is basically the same as that of the sheet-flow stack used in conventional electrodialysis, with the exception that the basic unit of an electrodialysis stack with bipolar membranes consists generally of three cells. Therefore, three separate flow streams must be fed through the manifold in the individual cells that form the repeating unit of the stack. The current density used in electrodialysis with bipolar membranes for the production of acids and bases is generally an order of magnitude higher than in most conventional electrodialysis applications. The voltage drop across a cell unit is also higher than in conventional electrodialysis because of the additional resistance of the bipolar membrane and the concentration potential between the reaction layer of the membrane and the outer phases. As a consequence of the high current density the cell unit area is usually significantly lower in bipolar membrane electrodialysis than that of conventional electrodialysis. Because of the higher voltage drop over a cell unit in electrodialysis with bipolar membranes the number of repeating cell units is also much lower than in conventional electrodialysis.

To design a bipolar membrane electrodialysis plant of a certain capacity and given feed solution and product requirements the necessary membrane area and the applied voltage must be determined. For a stack of three-cell units the required membrane area can be expressed as the cell unit area, which consists of a cation-exchange membrane, an anion-exchange membrane, and a bipolar membrane. The cell unit area is related to the total current required for the production of a certain amount of an acid and a base by the current density.

$$A_{\mathrm{cell}} = \frac{I}{i} \tag{4.43}$$

where A_{cell} is the cell unit area, I is the total current passing through the stack or stacks in series, and i is the average current density.

The total current for a certain production capacity is given by:

$$I = \frac{Q_{\mathrm{p}} F \Delta C_{\mathrm{p}}}{N_{\mathrm{cell}} \xi} \tag{4.44}$$

where Q_{p} is the total product flow, ΔC_{p} the concentration difference between the product solution in the feed at the entrance of the first stack and at the exit of the final stack, N the number of cell units in a stack, F the Faraday constant, and ξ the current utilization.

The average current density can be determined from the applied voltage and the resistance of the cell unit.

When concentration potentials between the three solutions are neglected the total voltage drop consists of three major contributions:

- The potential drop due to the water dissociation equilibrium
- The potential drop due to the resistance of the solutions
- The potential drop due to the resistance of the membranes

A cell unit contains the salt, the acid and base solutions, and the three membranes between these solutions. The total voltage drop is the sum of the water dissociation potential and the voltage drop due to the resistance of the solutions and membranes.

The voltage drop across a cell unit of a stack which consists of geometrically identical cells operated in cocurrent flow is given by:

$$U_{\mathrm{cell}} = \bar{i}\left[\Delta\left(\frac{1}{\Lambda_{\mathrm{s}}\overline{C}_{\mathrm{s}}} + \frac{1}{\Lambda_{\mathrm{b}}\overline{C}_{\mathrm{a}}}\right) + r^{\mathrm{tr}} + r^{\mathrm{am}} + r^{\mathrm{cm}} + r^{\mathrm{bml}}\right] + \frac{RT}{F}\ln\frac{C^{\mathrm{tr}}_{\mathrm{H}^+}C^{\mathrm{tr}}_{\mathrm{OH}^-}}{C^{\mathrm{b}}_{\mathrm{H}^+}C^{\mathrm{b}}_{\mathrm{OH}^-}} \tag{4.45}$$

where U_{cell} is the voltage drop across a cell unit, $\bar{i}$ the average current density along the cell in direction of the flow velocity parallel to the membrane surface, Δ the thickness of the individual cells, $\overline{C}$ the average concentration, Λ the equivalent conductivity, r the area resistance, R the gas constant, T the absolute temperature, F the Faraday constant, superscripts tr, am, cm, bml, and b refer to transition region, cation-exchange membrane, anion-exchange membrane, the two layers of the bipolar membrane, and the bulk solution, respectively, and subscripts s, a, and b to salt, acid, and base, respectively.

The average concentration is given by the integral average over the process path length. The average concentration for each ion is:

$$\overline{C}_i = \frac{C_i^{\mathrm{f}i} - C_i^{\mathrm{p}i}}{\ln\left(\frac{C_i^{\mathrm{f}i}}{C_i^{\mathrm{p}i}}\right)} \tag{4.46}$$

where $\overline{C}_i$ is the average concentration of ion i in a cell, $C_i^{\mathrm{f}i}$ and $C_i^{\mathrm{p}i}$ are the concentrations in the bulk solution at the cell entrance, i.e., the beginning of the process path length and the cell exit, i.e., the exit of the process path length.

Introducing Equation (4.46) into Equation (4.45) leads to:

$$U_{\mathrm{cell}} = \bar{i}\left[\Delta\left(\sum_i \frac{\ln\left(\frac{C_i^{\mathrm{f}i}}{C_i^{\mathrm{p}i}}\right)}{\Lambda_i\left(C_i^{\mathrm{f}i} - C_i^{\mathrm{p}i}\right)}\right) + r^{\mathrm{tr}} + r^{\mathrm{am}} + r^{\mathrm{cm}} + r^{\mathrm{bml}} + \frac{RT}{iF}\ln\frac{C^{\mathrm{tr}}_{\mathrm{H}^+}C^{\mathrm{tr}}_{\mathrm{OH}^-}}{\dfrac{C^{\mathrm{f}\mathrm{H}^+}_{\mathrm{H}^+} - C^{\mathrm{p}\mathrm{H}^+}_{\mathrm{H}^+}}{\ln\dfrac{C^{\mathrm{f}\mathrm{H}^+}_{\mathrm{H}^+}}{C^{\mathrm{p}\mathrm{H}^+}_{\mathrm{H}^+}}} \dfrac{C^{\mathrm{f}\mathrm{OH}^+}_{\mathrm{OH}^+} - C^{\mathrm{p}\mathrm{OH}^-}_{\mathrm{OH}^-}}{\ln\dfrac{C^{\mathrm{f}\mathrm{OH}^-}_{\mathrm{OH}^-}}{C^{\mathrm{p}\mathrm{OH}^-}_{\mathrm{OH}^-}}}}\right] \tag{4.47}$$

where U_{cell} is the voltage drop across a cell unit, $\bar{i}$ is the average current density in the cell unit, and subscript i refers to salt, acid, and base. All other symbols are as defined in Equations (4.44) and (4.45).

The required membrane area and the process path length for a given capacity plant and given feed solution and product concentrations as a function of the current density are derived from Equations (4.43) and (4.44):

$$A = \frac{Q_{\mathrm{p}}F\left(C_{\mathrm{p}}^{\mathrm{fp}} - C_{\mathrm{p}}^{\mathrm{p}}\right)}{\bar{i}\,\xi} \tag{4.48}$$

where A is the cell unit area, Q_{p} is the product volume flow, F is the Faraday constant, $C_{\mathrm{p}}^{\mathrm{fp}}$ and $C_{\mathrm{p}}^{\mathrm{p}}$ are the concentrations of the product at the cell entrance and the product at the cell exit, $\bar{i}$ is the average current density, ξ the current utilization, and N_{cell} the number of cell units in a stack.

For a given stack design and number of cell units in the stack the required process path length is given by:

$$L_{\mathrm{pp}} = \frac{A}{YN_{\mathrm{cell}}} \tag{4.49}$$

where L_{pp} is the process path length, Y the cell width, Q_{p} the product volume flow, F the Faraday constant, $C_{\mathrm{p}}^{\mathrm{fp}}$ and $C_{\mathrm{p}}^{\mathrm{p}}$ are the concentrations of the salt at the beginning and the end of the process path length; and N_{st} is the number of stacks in series.

4.6.1. *Operating Modes in Bipolar Membrane Electrodialysis*

There are several operating modes for the bipolar membrane stack. Depending on the feed solution concentration and the product requirements the process may be operated in a batch or continuous mode. In practical applications it is often operated in a feed-and-bleed mode as illustrated in Figure 38.

Figure 38. Flow scheme of a bipolar membrane electrodialysis stack operated in a feed-and-bleed mode, i.e., with partial recycling of the acid, the base, and the salt solution

With partial recycling of the acid, the base, and the salt solution a constant product concentration can be achieved by adjusting the feed and bleed streams and accordingly changing the recirculation rates of the acid, the base, and the salt solution flow streams.

4.6.2. *Energy Requirements in Electrodialytic Water Dissociation*

The energy required in electrodialytic water dissociation with bipolar membranes is the sum of three terms:

- The electrical energy required to transfer salt ions from the feed solution and protons and hydroxide ions from the bipolar membrane into the acid and base solutions.
- The energy required for the water dissociation in the bipolar membrane.
- The energy consumption for pumping the solutions through the stack.

Energy consumption due to electrode reactions can generally be neglected when more than 50 – 100 cell units are stacked between the two electrodes [72]. The energy required for the dissociation of water at constant temperature and pressure can be calculated for solutions with different H^+ ion activities (i.e., pH values). The Gibbs free energy required for the production of acids and bases in a bipolar membrane is:

$$\Delta G = -RT \ln \frac{C^{\mathrm{tr}}_{\mathrm{H}^+} C^{\mathrm{tr}}_{\mathrm{OH}^-}}{C^{\mathrm{b}}_{\mathrm{H}^+} C^{\mathrm{b}}_{\mathrm{OH}^-}} = -2.3\, RT \Delta\,\mathrm{pH} \tag{4.50}$$

where ΔG is the Gibbs free energy, R the gas constant, T the absolute temperature, F the Faraday constant, $C^{\mathrm{tr}}_{\mathrm{H}^+}$, $C^{\mathrm{tr}}_{\mathrm{OH}^-}$, $C^{\mathrm{b}}_{\mathrm{H}^+}$, and $C^{\mathrm{b}}_{\mathrm{OH}^-}$, are the proton and hydroxide ion concentrations in the transition region of the bipolar membrane and the bulk solutions in contact with the bipolar membrane, and ΔpH is the difference between the pH values of the two solutions separated by the bipolar membrane.

The Gibbs free energy for water dissociation varies slightly, depending on the salt being processed, the concentration of acid and base generated, and the temperature. For the production of 1 N acids and bases at 25 °C the theoretical free energy varies between 0.056 and 0.058 kW·h mol^{-1} and the electromotive force between 2.1 and 2.2 V.

4.6.3. *Total Energy Required for Production of an Acid and a Base*

The total energy required for acid and base production includes energy losses due to the resistances of the solutions and membranes and is given by the current passing through the stack multiplied by the total voltage drop encountered between the electrodes:

$$E_{\mathrm{pro}} = I\,U\,t \tag{4.51}$$

where E_{pro} is the energy consumed in a stack for the production of an acid and a base, I the current passing through a stack or a series of stacks, U the voltage applied across the stack (i.e., between the electrodes), and t the operating time.

The voltage drop in a stack arrangement is caused by the electrical resistances of the solutions and the membranes in the stack and by the potentials which are established between solutions of different ion concentrations. The voltage drop per cell unit under the assumption that the stacks consist of geometrically identical cells which are operated in cocurrent flow with equal velocity is given by Equation (4.47). The required current for the production of a given amount of acid and base is given by Equation (4.44). Introducing Equations (4.44) and (4.47) into Equation (4.51) and considering the voltage drop across the entire stack, the total energy for the production of a given amount of acid and base from the corresponding salt solution is given by:

$$E_{\mathrm{pro}} = I\,N_{\mathrm{cell}}\,U_{\mathrm{cell}}\,t = N_{\mathrm{st}}\bar{i}\left(\frac{\Delta}{\sum_i \Lambda \overline{C}_i} + r^{\mathrm{tr}} + r^{\mathrm{am}} + r^{\mathrm{cm}} + r^{\mathrm{bml}} + \frac{2.3\,RT\overline{\Delta}\mathrm{pH}}{\bar{i}\,F}\right)\left(\frac{Q_p F\left(C^{\mathrm{fp}}_{\mathrm{p}} - C^{\mathrm{p}}_{\mathrm{p}}\right)}{N_{\mathrm{cell}}\,\xi}\right) t \tag{4.52}$$

where E_{pro} is the energy for the production of a certain amount of acid and base, I the current passing through the stack, N_{cell} the number of cell units in a stack, U_{cell} the voltage drop across a cell unit, $\bar{i}$ the average current density, Δ the thickness of the individual cells, $\overline{C}_i$ the average concentration, Λ_i the equivalent conductivity, r the area resistance, ξ the current utilization, R the gas constant, T the absolute temperature, F the Faraday constant, $\overline{\Delta}$ pH the average difference in the pH value between the solution in the transition region of the bipolar membrane and the two adjacent bulk solutions, subscript i refers to salt, acid, and base, superscripts tr, am, cm, and bml to the transition region, the cation-exchange membrane, the anion-exchange membrane, and the two layers of the bipolar membrane, C_p^{fp} and C_p^{p} are the concentrations of the acid or base at the cell inlet and the cell outlet, Q_p is the total flow of the acid or base through the stack, and t the time.

The total current I passing through the stack, which is identical to the current through a cell unit, is related to the average current density $\bar{i}$ and the area of a cell A_{cell} unit by:

$$I = \frac{Q_p F\left(C_p^{fp} - C_p^{p}\right)}{N_{st}\,\xi} = \bar{i}\,A_{cell} \tag{4.53}$$

Introducing Equation (4.53) into (4.52) gives the energy for the production of a certain amount of acid and base:

$$E_{pro} = N_{st}\,A_{cell}\left(\frac{\Delta}{\sum_i \Lambda \overline{C}_i} + r^{tr} + r^{am} + r^{cm} + r^{bml} + \frac{2.3\,RT\overline{\Delta}\mathrm{pH}}{\bar{i}\,F}\right)\left(\frac{Q_p F\left(C_p^{fp} - C_p^{p}\right)}{A_{cell}\,N_{st}\,\xi}\right)^2 t \tag{4.54}$$

where the symbols are as defined in Equation (4.52).

The term $\frac{Q_p F\left(C_p^{fp} - C_p^{p}\right)}{A_{cell}\,N_{st}\,\xi}$ is identical to the current density. This means that for a given stack design the acid and base production energy E_{pro} is proportional to i^2.

The average concentrations of the acid, the base, and the salt in the bulk solutions $\overline{C}_i$ can be expressed by an integral average of the solutions at the cell inlet and the cell outlet C_i^{fi} and C_i^{pi}, respectively, as indicated by Equation (4.47). Thus, the electrical energy consumption for the production of an acid and a base in electrodialytic water dissociation with bipolar membranes can by calculated as a function of the applied current density, the produced acid and base concentrations, and the volume of acid and base, and by the current utilization, which is affected by hydraulic leaks between the cells, current flow through the manifold system, and transport of co-ions, especially protons and hydroxide ions, through membranes that are not strictly permselective. All these effects are expressed in the current utilization ξ.

4.6.4. *Total Process Costs*

The estimation of the total production costs in bipolar membrane electrodialysis follows the general procedure applied in conventional electrodialysis. The main difference is that in addition to the monopolar membranes bipolar membranes are needed and that the energy costs are increased by the additional energy required for water dissociation in the bipolar membrane.

Furthermore, the applied current density is only limited by water diffusion into the bipolar membrane and is generally significantly higher than in conventional electrodialysis. The optimum operating current density in bipolar membrane electrodialysis in practical applications is on the order of 1000 A m^{-2} [80].

4.7. Continuous Electrodeionization Process Design

Continuous electrodeionization is widely used today to produce high-quality deionized water for the preparation of ultrapure water in the electronics industry and in analytical laboratories [81-83].

The process design and the different hardware components needed in electrodeionization are very similar to those used in conventional electrodialysis. The main difference is the stack construction. The diluate cell, and sometimes also the concentrate cell, is filled with an ion-exchange resin, which affects the flow distribution and the pressure drop of the solution in the cell drastically. Therefore, the dimensions of the diluate and concentrate cells are generally quite different. The different concepts used for the distribution of the cations and anions in the cell are illustrated in Figure 39. In the conventional electrodeionization process the diluate cell is filled with a bed of mixed ion-exchange resins with a ratio of cation- to anion-exchange resin close to 1, as shown in Figure 39a. The cation- and anion-exchange resins can also be placed in separate beds in series in a stack as is illustrated in Figure 39b. The main difference between the electrodeionization system with the mixed ion-exchange resin bed and the system with separate beds is that in mixed-bed electrodeionization systems anions and cations are simultaneously removed from the feed while the solution leaving the diluate cell is neutral. In the electrodeionization system with separate anion- and cation-exchange beds the anions are first exchanged by the hydroxide ions generated at the cathode, and the solution leaving the cation-exchange bed is basic. This solution is then passed through the cell with the cation-exchange resin, where the cations are exchanged by the protons generated at the anode. At the exit of the cation-exchange cell the solution is again neutral. The production of the H^+ and OH^- ions can also be accomplished by bipolar membranes instead of electrodes [84].

Figure 39. Schematic illustrating two different stack concepts used in continuous electrodeionization. a) A stack in which a repeating unit consists of a diluate cell filled with a mixed bed of ion-exchange resins and a concentrate cell; b) A repeating unit of a stack with a concentrate cell between two diluate cells, one filled with a cation-exchange resin and the other with an anion-exchange resin, between two electrodes

4.8. Other Membrane Processes

Ion-exchange membranes are used as fuel cell separators and in combination with electrochemical reactions in electrochemical synthesis such as the production of chlorine and alkali [85].

Facilitated-transport and membrane reactors are still in an early state of development and so far used mainly on a laboratory scale. The same is true for membrane distillation and membrane contactors.

[Top of Page]

5. Membrane Preparation and Membrane Module Constructions

The most important part in any membrane separation process is the membrane itself. As described in Section Materials and Structures of Synthetic Membranes membranes vary widely in structure, function, transport properties, transport mechanism, and the materials from which they are made. Just as diverse as the different membranes are the methods of making them. Some membranes are manufactured by simple sinter techniques from fine powders, others are prepared by irradiation and track etching of thin films or by inversion of homogeneous liquid mixtures or melts into heterogeneous solid phases. Composite membranes are prepared by dip-coating techniques, interfacial polymerization, and plasma polymerization. Inorganic membranes are prepared as composite structures by using powder sintering techniques and the sol – gel method. Liquid membranes with mobile selective carriers are prepared as emulsions or supported in porous structures. Fixed-carrier and ion-exchange membranes are prepared by introducing positively or negatively charged groups into suitable polymer structures.

Closely related to preparation of membranes is their characterization. In addition to the determination of their transport properties, membranes are also characterized by various methods in terms of their morphology and their mechanical, chemical, and electrochemical properties. Which of the different membrane characterization techniques are used depends on the membrane type and its possible application.

5.1. Membrane Preparation

The selection of a suitable base material and preparation technique depends on the application the membrane is to be used in. In some applications such as gas separation and pervaporation the membrane material used as the barrier layer is of prime importance for the performance of the membrane. In other applications such as micro- and ultrafiltration the membrane material is not quite as important as the membrane structure. Membrane preparation procedures are often developed empirically and described in the literature as detailed recipes [17, 86-89].

5.1.1. *Preparation of Porous Membranes*

Porous membranes consist of a solid matrix with defined pores which have diameters ranging from less than 2 nm to more than 20 µm. They can be made from various materials, such as ceramics, graphite, metal, metal oxides, and polymers. Their structure may be symmetric (i.e., pore diameters do not vary over the membrane cross section) or asymmetric (i.e., pore diameters increase from one side of the membrane to the other by a factor of 10 – 1000. Porous membranes are used mainly in microfiltration and ultrafiltration. They can be classified according to:

- The material they are made from
- Their structure (symmetric or asymmetric)
- Their pore size and pore size distribution

The membrane material determines the mechanical properties and the chemical stability of the membrane. The chemical properties of the material such as its hydrophilicity or hydrophobicity affect its performance in a practical application due to specific adsorption of constituents of the feed mixture.

The methods used most widely today for making porous membranes are sintering of powders, stretching of films, irradiation and etching of films, and phase inversion or sol – gel processes. The different structures, the material from which they are made, their preparation, and their typical applications are summarized in Table 2.

Table 2. Porous membranes and their preparation and applications

Membrane type	Membrane material	Pore size, µm	Preparation process	Applications
Symmetric	ceramic, metal, polymer, graphite	0.1 – 20	powder pressing and sintering	microfiltration, gas separation
Symmetric	polymer with partial crystallinity	0.2 – 10	extruding and stretching of films	microfiltration, battery separator
Symmetric	polymer, mica	0.05 – 5	irradiation and etching of films	microfiltration, point-of-use filters
Symmetric	polymer, metal, ceramic	0.5 – 20	template leaching of films	microfiltration
Symmetric	polymer	0.5 – 10	temperature-induced phase inversion	microfiltration
Asymmetric	polymer	< 0.01	diffusion-induced phase inversion	ultrafiltration
Asymmetric	ceramic	< 0.01	composite-membrane gel – sol process	ultrafiltration

Sintering is a rather simple technique to obtain porous structures from organic and inorganic materials. A powder consisting of particles of a certain size is pressed into a film or plate and sintered just below the melting point of the material. Figure 40a

shows the surface of a porous membrane made by pressing and sintering a plate of fine polytetrafluoroethylene powder. The process yields a porous structure of relatively low porosity in the range of 10 – 40 %, and a rather irregular pore structure with a very wide pore size distribution. Material selection for the preparation of sintered membranes is determined mainly by the required mechanical properties and chemical and thermal stability of the material in the application of the final membrane. Sintered membranes are made on a large scale from ceramic materials such as aluminum oxides, graphite, and metal powders such as stainless steel and tungsten. The particle size of the powder is the main parameter determining the pore sizes of the final membrane, which typically range from 0.2 to 20 µm. The lower limit of the pore diameter is determined by the particle size of the powder. Sintered membranes can be made in the form of disks, cartridges, or fine-bore tubes. They are used for the filtration of colloidal solutions and suspensions. They are also suitable for gas separation and widely used for the separation of radioactive isotopes.

Figure 40. Scanning electron micrographs of a) a sintered membrane prepared from a polymer powder, b) a membrane prepared by stretching an extruded polytetrafluoroethylene film perpendicular to the direction of extrusion, and c) a capillary-pore polycarbonate membrane made by track etching

Porous carbon membranes are also prepared by *pyrolysis* of preformed polyacrylonitrile membranes in an inert atmosphere at 600 – 800 °C. The membranes are generally coated on a porous ceramic support or prepared as hollow fibers. Their pore size is 1 – 4 nm. The membranes are used for both ultrafiltration and gas separation. However, they are very brittle and thus difficult to handle in large-scale practical applications.

Another relatively simple procedure for preparing porous membranes is the *stretching* of a homogeneous polymer film with partial crystallinity [90]. This technique is mainly employed with films of polyethylene or polytetrafluoroethylene which have been extruded from a polymer powder at temperatures close to its melting point and rapidly drawn down. The crystallites in the semicrystalline polymer are aligned in the direction of drawing. After annealing and cooling the extruded film is stretched perpendicular to the drawing direction. This leads to partial fracture of the film, and relatively uniform pores with diameters of 0.2 – 20 µm are obtained. A typical stretched membrane prepared from polytetrafluoroethylene is shown in Figure 40b. The membranes can be produced as flat sheets, tubes, and capillaries. Because of the hydrophobic nature of the polymer these membranes are highly permeable for gases and vapors but impermeable for aqueous solutions. They are used in sterile filtration, blood oxygenation, and membrane distillation, and as water-repellent textiles. Because of its high porosity this membrane has a high gas and vapor permeability, but up to a certain hydrostatic pressure it is completely impermeable to aqueous solutions.

Porous membranes with very uniform, nearly perfectly round cylindrical pores are obtained by *track etching* [91]. In the first step, a homogeneous 6 – 15 µm thick polymer film is exposed to collimated charged particles in a nuclear reactor. As particles pass through the film, they leave sensitized tracks where the chemical bonds in the polymer backbone are damaged. In the second step, the irradiated film is placed in an etching bath, in which the damaged material along the tracks is preferentially etched to form uniform cylindrical pores. The pore density of a track-etched membrane is determined by the residence time in the irradiator, while the pore diameter is controlled by the residence time in the etching bath. The minimum pore diameter of these membranes is approximately 0.01 µm. The maximum pore size that can be achieved in track-etched membranes is determined by the etching procedure and is about 5 µm. Figure 40c shows a typical track-etched polycarbonate membrane. Capillary-pore membranes are prepared today mainly from polycarbonate and polyester films. The advantage of these polymers is that they are commercially available in very uniform films of 10 – 15 µm thickness, which corresponds to the maximum penetration depth of collimated particles from a nuclear reactor. Because of their narrow pore size distribution and low tendency to plug, capillary-pore membranes made from polycarbonate and polyester have found applications on a large-scale in analytical chemistry and microbiological laboratories, and in medical diagnostic procedures. Capillary-pore membranes are used on an industrial scale for the production of ultrapure water for the electronics industry. Here, they show certain advantages over other membrane products because of their short “rinse down” time and good long-term flux stability. Because of their surface filter characteristics, particles retained by the membranes can be further monitored by optical or scanning electron microscopy.

Other techniques to produce porous microfiltration membranes are based on *microlithography* and *template leaching*. These membranes often have a narrow pore size distribution and high fluxes. The template-leaching technique is also applied to prepare membranes from glass, metal alloys, and ceramics [92]. The preparation procedure for porous glass and metal membranes is relatively simple: Two different types of glass or metals are homogeneously mixed; then, one type is dissolved and a network with well-defined pore sizes of the undissolved material is obtained.

Most commercially available symmetric microporous membranes are prepared by the *phase-inversion process* in which a polymer is dissolved in an appropriate solvent and spread as a 20 – 200 µm thick film on a plate, a belt, or a fabric support. A precipitant such as water is added to this liquid film and causes separation of the homogeneous polymer solution into a solid polymer-rich and a liquid solvent-rich phase. The precipitated polymer forms a porous structure containing a network of more or less uniform pores. A microporous cellulosic membrane made by phase inversion is shown in Figure 41a.

Figure 41. Scanning electron micrograph of the surface of a) a porous cellulose nitrate membrane prepared from a homogeneous polymer solution by precipitation with water vapor, and b) a porous polypropylene membrane precipitated by thermal gelation from a hot polymer solution

Porous phase-inversion membranes can be made from almost any polymer which is soluble in an appropriate solvent and

can be precipitated in a nonsolvent. By varying the polymer, the polymer concentration, the precipitation medium, and the precipitation temperature, porous phase-inversion membranes can be made with a very large variety of pore sizes, from less than 0.1 to more than 20 µm, and with varying chemical and mechanical properties. These membranes were originally prepared from cellulosic polymers by precipitation at room temperature in an atmosphere of approximately 100 % R.H. More recently, symmetric microporous membranes have also been prepared from various polyamides, polysulfone, and poly (vinylidene difluoride) by precipitation of a cast polymer solution in water. The phase-inversion process is today the most important technique for obtaining porous structures. Polypropylene or polyethylene can also be used for the preparation of porous membranes. However, since these polymers are not readily dissolved at room temperature, the preparation technique must be slightly varied. Polypropylene, for example, is dissolved in an appropriate amine at elevated temperatures. A solution of 20 – 30 % polymer is spread at elevated temperature into a film. The precipitation of the polymer, however, is not induced by the addition of a nonsolvent but merely by cooling the solution to a point at which a two-phase system forms. The resulting open foam structure is shown in Figure 41b. The pore size of membranes depends on the polymer concentration, the solvent system, the solution temperature, and the cooling rate. This membrane preparation technique is usually referred to as *thermal gelation*.

The symmetric, porous polymer membranes made by phase inversion are widely used for separations on laboratory and industrial scale. Typical applications range from the clarification of turbid solutions to the removal of bacteria or viruses, the detection of pathological components, and the detoxification of blood in artificial kidneys. The separation mechanism is that of a typical depth filter which traps the particles somewhere within the structure. In addition to the simple “sieving” effect, porous phase-inversion membranes often show a pronounced tendency for adsorption because of their extremely large internal surface area. They are therefore particularly well suited when complete removal of components such as viruses or bacteria is desired. They are suited for immobilization of enzymes for use in biotechnology. They are also widely used for culturing microorganisms in water quality control tests.

5.1.2. *Preparation of Asymmetric Membranes*

Most membranes used today in large-scale separation processes have an asymmetric structure which consists of a very thin (0.1 – 1 µm) selective skin layer on a highly porous, ca. 100 – 200 µm thick substructure (Fig. 42). The very thin skin represents the actual membrane. It can consist of homogeneous polymer or can contain pores. Its separation characteristics are determined by the nature of the polymer or the pore size in the skin, while the mass transport rate is determined by the thickness of the skin. The porous substructure serves only as a support for the thin and sometimes fragile skin and has little effect on separation characteristics or the mass transfer rate of the membrane.

Figure 42. Scanning electron micrographs showing cross sections of a) an asymmetric reverse osmosis membrane with a graded pore structure and b) an asymmetric ultrafiltration capillary membrane with a finger-type structure

Asymmetric membranes are used primarily in pressure-driven membrane processes such as reverse osmosis, ultrafiltration, and gas separation, as it is here that the unique properties of high mass transfer rates combined with good mechanical stability can be best utilized. In addition to high filtration rates, asymmetric membranes are very resistant to fouling. Conventional symmetric structures act as depth filters and retain particles within their internal structure. These trapped particles plug the membrane, and so the flux declines during use. Asymmetric membranes are surface filters and retain all rejected materials at the surface where they can be removed by shear forces applied by the feed solution moving parallel to the membrane surface. Two techniques are used to prepare asymmetric membranes: One technique utilizes the phase-inversion process and leads to a membrane in which the skin and the substructure consist of the same polymer (integral asymmetric membrane). In the second technique an extremely thin polymer film is deposited on a preformed porous substructure to give composite membranes. The development of the first integral asymmetric membranes by phase inversion was a major breakthrough in the development of ultrafiltration and reverse osmosis. These membranes were made from cellulose acetate and yielded fluxes 10 – 100 times higher than symmetric structures with comparable separation characteristics. Today, however, most reverse osmosis membranes are composite structures.

Asymmetric phase-inversion membranes can be prepared from virtually all polymers that are soluble at a certain temperature in an appropriate solvent or solvent mixture and can be precipitated as a continuous solid phase by either changing the temperature or the composition of the system by the following general procedures [93-97]:

- Cooling of a homogeneous polymer solution which separates at a certain temperature into two phases.
- Evaporation of a volatile solvent from a homogeneous polymer solution with two or more solvents of different dissolution capacity.
- Addition of a nonsolvent or nonsolvent mixture to a homogeneous solution.

All three procedures result in the formation of two phases, that is, a liquid phase that forms the membrane pores and a solid phase that forms the membrane structure, which may be either symmetric and porous or asymmetric with a dense skin on one or both surfaces of a porous bulk phase. The only thermodynamic prerequisite for all three preparation procedures is that the system has a miscibility gap over a defined concentration and temperature range.

A phase separation that is the result of a temperature change is called temperature-induced phase separation, and a phase separation caused by the addition of a nonsolvent or nonsolvent mixture to a homogeneous solution is referred to as diffusion-induced phase separation. In practical membrane preparation combinations and certain variations of the basic

processes are used to produce membranes with tailor-made structures and properties.

The *diffusion-induced phase-separation process* consists of the following consecutive steps:

- A polymer is dissolved in an appropriate solvent to form a solution.
- The solution is cast into a film on the order of 100 – 500 µm thickness.
- The film is quenched in a nonsolvent, typically water or an aqueous solution.

During the quenching process the polymer solution separates into two phases: a polymer-rich solid phase which forms the membrane structure, and a solvent-rich liquid phase which forms the liquid-filled membrane pores. Generally, the pores at the film surface, where precipitation occurs first and most rapidly, are much smaller than in the interior or on the bottom side of the film. This leads to the asymmetric membrane structure.

Different variations on this general preparation procedure are described in the literature. For example, sometimes an evaporation step prior to the precipitation is used to change the composition in the surface of the cast film, and an annealing step is applied to change the structure of the precipitated membrane [98], [99].

The original recipes and subsequent modifications for preparing asymmetric membranes are deeply rooted in empiricism. Detailed descriptions of membrane preparation techniques are given in the literature [93, 100-103]. Only after extensive use of the scanning electron microscope, which provided the necessary structural information, was it possible to rationalize the various parameters responsible for the processes forming the membrane structure. It then became evident that both symmetric and asymmetric porous structures can be prepared by the diffusion-induced phase-separation process from a large number of polymers when the appropriate preparation parameters are chosen. The actual phase separation or phase inversion can be induced not only by addition of nonsolvent but also by controlled evaporation of a volatile solvent from a three-component mixture of solvent – precipitant – polymer, causing precipitation as the system becomes enriched in precipitant [104]. Alternatively, precipitation of a simple two-component polymer – solvent casting solution can be brought about by imbibing precipitant from the vapor phase [17]. This technique was the basis of the original porous membranes and is still used commercially today by several companies.

In the *temperature-induced phase-separation process* the precipitation of a casting solution is achieved by cooling a polymer solution which forms a homogeneous solution only at elevated temperature, for example polypropylene dissolved in *N,N*-bis-(2-hydroxyethyl)tallow amine [95]. The temperature-induced phase-separation process generally results in a symmetric porous structure. Under certain experimental conditions it can also result in asymmetric structures [97]. Temperature-induced phase separation is not only applicable to polymers. It is also used for the preparation of porous membranes from glass mixtures and metal alloys in combination with a leaching procedure.

5.1.3. *Rationalization of the Phase-Inversion Membrane Preparation Process*

Although the recipes given in the literature for the preparation of porous structures from polymers, metals, or glasses by phase inversion are very different they are all based on similar thermodynamic and kinetic parameters, such as the chemical potentials and diffusivities of the individual components and Gibbs free energy of mixing of the entire system. Identification of the various process parameters is the key to understanding the mechanism of membrane formation, which is a necessity for optimizing membrane properties and structures.

A quantitative treatment considering all thermodynamic and kinetic parameters involved in the phase-inversion process is difficult. But a phenomenological description of the process with the aid of the phase diagram of a mixture consisting of a polymer and one or more solvents and nonsolvents at constant or different temperatures is very useful for a better understanding of the relation between membrane structure and the different preparation parameters. However, the phase diagram is the thermodynamic description of an equilibrium state. In the membrane formation process phase separation is also determined by kinetic parameters, and thermodynamic equilibrium is generally not attained on a macroscopic scale. The quantitative description of the kinetics is difficult. However, a general thermodynamic description of the phase separation based on the phase diagram of the polymer – solvent – nonsolvent system provides valuable information concerning the membrane structures obtained by the phase-inversion process.

Temperature-induced phase separation of a two-component polymer mixture is illustrated in Figure 43a, which shows a phase diagram of a two-component mixture of a polymer and a solvent as a function of temperature. The diagram indicates a miscibility gap over a wide range of composition at low temperature. Above a certain temperature the polymer and solvent form a homogeneous solution at all compositions. At other temperatures the system is not stable at certain compositions and will separate into two phases. This region is referred to as the miscibility gap, which is surrounded by the binodal curve. If a homogeneous polymer – solvent mixture of a certain composition at temperature T_1, as indicated by point A in Figure 43a, is cooled to temperature T_2, as indicated by point B, it will separate into two different phases, the composition of which is indicated by points B′ and B″. Point B″ represents the polymer-rich phase and point B′ the solvent-rich polymer-lean liquid phase. The lines B′ – B and B″ – B represent the ratio of the amounts of the two phases in the mixture, that is, the overall porosity of the obtained porous system. When the polymer concentration in the polymer rich phase has reached a certain value its viscosity has increased to such an extent that it can be considered as solid. The polymer-rich phase forms the solid membrane structure and the polymer-lean phase the liquid-filled pores.

Figure 43. Schematic showing the formation of a microporous system by a) thermal precipitation of a two-component mixture and b) by addition of a nonsolvent to a homogeneous polymer solution in a three-component mixture exhibiting a miscibility gap under certain conditions of temperature and composition

Phase separation induced by the addition of a nonsolvent to a homogeneous polymer solution is illustrated in Figure 43b, which shows a three-component isothermal phase diagram. The three-component mixture exhibits a miscibility gap over a wide range of compositions. If a nonsolvent is added to a solution consisting of polymer and solvent with composition indicated by point A on the solvent – polymer line and the solvent is removed from the mixture at about the same rate as the nonsolvent enters, the composition of the mixture will change following the line A – B. When the composition of the system reaches the miscibility gap it will separate into two phases: a polymer-rich phase represented by the upper boundary of the miscibility gap which is determined by the binodal curve, and a polymer-lean phase represented by the lower boundary of the miscibility gap. When the solvent is replaced completely by the nonsolvent the mixture reaches the composition represented by point B. Point B represents a mixture of the solid polymer-rich phase and a liquid polymer lean phase of compositions B′ and B″, respectively. Instead of adding a nonsolvent to a polymer – solvent mixture, phase separation can also be achieved by evaporation of a solvent from a solvent – polymer – nonsolvent mixture which is used as casting solution for the membrane [104].

The description of the formation of porous systems by means of the phase diagrams, as illustrated in Figure 43, is based on the assumption of thermodynamic equilibrium. It predicts under which conditions of temperature and composition a system will separate into two phases. But it does not provide any information on the size of the domains of the two phases and their shapes, that is, the pore size, the pore shape (i.e., “finger”- or “sponge”-like), and the pore size distribution of the membrane. These parameters are determined by kinetic parameters such as the diffusivities of the various components in the mixture, the viscosity of the solution, and the chemical potential gradients which act as driving forces for the diffusion of the various components in the mixture. Because these parameters change continuously during phase separation, which constitutes the actual membrane formation process, no transient states of equilibrium will be achieved. Therefore, the kinetic parameters are difficult to determine by independent experiments and thus are not readily available. This makes a quantitative description of the membrane formation mechanism very difficult.

By the phase-inversion process both symmetric and asymmetric membranes with rather different structures are produced commercially from a variety of polymers (Table 3).

Table 3. Polymers used for commercial membrane production by phase inversion and their applications

Membrane material	Membrane processes[a]
Cellulose acetate	EP, MF, UF, RO
Cellulose esters (mixed)	MF, D
Polyacrylonitrile (PAN)	UF
Polyamide (aromatic, aliphatic)	MF, UF, RO
Polyimide	UF, RO, GS
Polypropylene	MF
Polyethersulfone	UF, MF, GS, D
Polysulfone	UF, MF, GS, D
Sulfonated polysulfone	UF, RO, NF
Poly(vinylidene fluoride)	UF

[a]D = dialysis, EP = electrophoresis, GS = gas separation, MF = microfiltration, NF = nanofiltration, RO = reverse osmosis, UF = ultrafiltration.

5.1.4. *Preparation of Composite Membranes*

In processes such as reverse osmosis, gas separation, and pervaporation, the actual mass separation is achieved by a solution-diffusion mechanism in a homogeneous polymer layer. Since the diffusion process in a homogeneous polymer matrix is relatively slow, these membranes should be as thin as possible. Therefore, an asymmetric membrane structure is mandatory for these processes. Unfortunately, many polymers with satisfactory selectivities and permeabilities for the various components in gas mixtures or liquid solutions are not well suited for the phase-inversion membrane preparation process. This has led to the development of the composite membranes. A typical composite membrane is shown schematically and as a scanning electron micrograph in Figure 44. It is composed of a 20 – 1000 – nm thick dense polymer barrier layer formed over an approximately 50 – 100 µm thick porous film. Composite membranes are prepared in a two step process: 1) manufacture of the porous support, and 2) deposition of the barrier layer on the surface of this porous support layer.

Figure 44. a) Schematic of a composite membrane showing the porous support structure and the selective skin layer, and b) scanning electron micrograph of a composite membrane with polydimethylsiloxane as the selective layer on a polysulfone support structure

The advantages of composite membranes over integral asymmetric structures is that different polymers can be used for the porous support and the selective barrier layer. This means that polymers which show the desired selectivity for a certain separation problem but are not suited for fabrication into integral asymmetric membranes because of poor mechanical strength or poor film-forming properties, may be usable as the selective barrier in composite membranes. And polymers suited for the preparation of porous structures but without the required properties for a certain separation task can be used as support structure. This expands the variety of available materials for the preparation of membranes with properties required for a given separation task considerably.

Making composite membranes involves two steps. One is the preparation of a suitable porous support and the second is the preparation of the actual barrier layer on the surface of the support structure. The performance of a composite membrane is not only determined by the properties of the selective barrier layer, but it is also significantly affected by properties of the porous support. Although the selectivity of a composite membrane is determined almost exclusively by the actual barrier layer, its flux rate is also to some extent determined by the pore size and overall porosity of the substructure. The effect of pore size and overall porosity is illustrated in Figure 45, which shows an idealized homogeneous barrier layer on a porous support.

The actual diffusion pathway of the component through the barrier layer into a pore of the support structure is always longer than the thickness of the barrier layer z_o but shorter than the longest path z_{max}.

Figure 45. Schematic illustrating the diffusion path of a component through a selective barrier layer of a composite membrane (z_o represents the shortest and z_{max} the longest path)

If it is assumed that the transport in the support structure is exclusively through the pores the effective path length can be expressed as a function of the overall membrane porosity, the thickness of the barrier layer, and the radius of the pores in the support structure:

$$z_{\mathrm{eff}} = \omega z_o + (1-\omega)\frac{1}{2}\left(\sqrt{r^2\left(\frac{1-\omega}{\omega}\right)} + z_o^2 + z_o\right) \tag{5.1}$$

where z_{eff} and z_o are the effective diffusion path length and the thickness of the barrier layer, respectively, r is the radius of the pores in the support structure, and ω the surface porosity of the support structure.

This relationship, which can be obtained by simple geometric considerations [68], indicates that the effective diffusion path length z_{eff} is strongly affected by the surface porosity of the substructure. According to Equation 5.1 the effective diffusion length is approximately equal to the thickness of the barrier layer at relatively high surface porosity (> 50 %). However, it increases by an order of magnitude when the porosity is less than 1 % if the barrier layer thickness is assumed to be approximately the same as the pore radius. Accordingly, the flux decreases by the same magnitude. The geometrical consideration expressed in Equation 5.1 indicates that the surface porosity of the support layer significantly affects the membrane flux. The porosity should always be as high as possible to achieve optimal flux rates with thin-film composite membranes. To ensure adequate mechanical strength, the pore diameter should not be significantly greater than the film thickness.

The techniques used for the preparation of composite membranes can be grouped into four general procedures:

- Casting of the barrier layer, for example, on the surface of a water bath and then laminating it on the porous support film.
- Coating of the porous support film by a polymer, a reactive monomer, or prepolymer solution followed by drying or curing with heat or radiation.
- Gas-phase deposition of the barrier layer on the porous support film from a glow-discharge plasma.
- Interfacial polymerization of reactive monomers on the surface of the porous support film.

Casting an ultrathin film of cellulose acetate on a water surface and transferring the film onto a porous support was one of the earliest techniques used for preparing composite reverse osmosis membranes. However, this technique is no longer used today [30].

Coating a porous support structure by dipping it into a polymer or prepolymer solution is today applied mainly for the preparation of composite membranes to be used in gas separation and pervaporation. In particular, polymers such as polydimethylsiloxane which are available as soluble prepolymers and which can easily be cross-linked by heat treatment and thus become insoluble in most solvents are suited for the preparation of this type of composite membrane. If the pore dimension in the support membrane is selected properly, the prepolymer is unable to penetrate the support, and a rather thin uniform barrier layer of 0.05 – 1 µm thickness can easily be prepared. A typical composite membrane prepared by dip coating can be seen in Figure 44b, which shows a scanning electron micrograph of an asymmetric polysulfone ultrafiltration membrane which was coated with a 1 wt % solution of polydimethylsiloxane in an appropriate solvent followed by thermal cross-linking [68].

Gas-phase deposition of a barrier layer on a dry porous support membrane by plasma polymerization was also successfully used for the preparation of reverse osmosis membranes. Although reverse osmosis membranes with excellent desalination properties showing salt rejection in excess of 99 % and fluxes of 1.2 $m^3\ m^{-1}\ d^{-1}$ when tested with seawater have been prepared on a laboratory scale by plasma polarization, it is not used in large-scale industrial production of composite membranes [105].

Today, by far the most important technique for preparing composite membranes is *interfacial polymerization of reactive monomers* on the surface of a porous support film. The first membrane produced on a large scale with excellent reverse osmosis desalination properties was developed in the early seventies in the North Star Research Institute under the code name NS 100 [106, 107]. The preparation procedure of this membrane, which exhibited water fluxes of about 1 $m^3\ m^{-1}\ d^{-1}$ and salt rejections in excess of 99 % when tested with seawater at 6 MPa pressure, was rather simple [108]. A polysulfone support membrane was soaked in an aqueous solution of 0.5 – 1 % polyethyleneimine, which was treated interfacially at the membrane surface with a 0.2 – 1 % solution of toluene diisocyanate in hexane. A heat curing step at 110 °C leads to further cross-linking of the polyethyleneimine. The preparation of composite membranes based on piperazine and trimesoyl chloride is shown schematically in Figure 46.

Figure 46. Schematic showing the formation of a composite membrane by interfacial polymerization of piperazine with trimesoyl chloride

The process seems to involve two types of reactions. In a first step, the piperazine reacts rapidly at the interface with the trimesoyl chloride to form a polyamide surface skin, while amino groups below this surface remain unconverted. In the second, heat-treatment step, internal cross-linking of these amino groups takes place. Thus, the final membrane has three distinct layers of increasing porosity: 1) the dense polyamide surface skin, 2) a thin cross-linked piperazine layer which extends into the pores of the support film, and 3) the actual polysulfone support membrane.

5.1.5. *Preparation of Inorganic Composite Membranes*

Ceramic membranes for use in micro-, ultra-, and nanofiltration as well as in pervaporation and gas separation are also prepared as multilayer composite structures [109]. A typical three-layer structure of an ultra- or nanofiltration membrane is shown schematically in Figure 47a and as a scanning electron micrograph in Figure 47b. The first support layer is generally prepared from a suspension of Al_2O_3 powder by using an organic polymer such as cellulose or poly(vinyl alcohol) as a binder and to increase the viscosity of the suspension. The suspension can be processed by slip casting or extrusion into flat sheets, hollow fibers, or tubes to form the so-called green structure, which is dried and converted into the final membrane by sintering at about 1500 °C to give a porous structure of α-Al_2O_3 with an average pore diameter of 5 µm or more and an overall porosity of about 35 %. The process is shown in Figure 48. A second layer, prepared by a sol – gel process, is deposited on the support layer by dip coating or filtration. The sol used in this process consists of colloidal particles, as indicated in the schematic of Figure 49. The material used for the preparation of the second layer is usually γ-Al_2O_3 or TiO_2. The pore size of this layer is in the range of 5 – 10 nm. Thus, the two-layer membrane can be used for micro- and ultrafiltration applications. For the separation of lower molecular weight components in nanofiltration and pervaporation a third layer is deposited. This layer is also prepared by the sol – gel process. However, the sol contains an inorganic polymer, as indicated in Figure 49, which becomes a polymer gel consisting of a three dimensional network. As material for the inorganic polymer structure TiO_2, ZrO_2, or SiO_2 is often used.

Figure 47. a) Schematic illustrating the structure of a three-layer inorganic composite membrane, and b) scanning electron micrograph of a three-layer ceramic membrane

Figure 48. Porous inorganic membrane preparation scheme based on slip casting of a ceramic powder and sintering at 1500 – 1800 °C

Figure 49. Schematic illustrating the colloidal and polymeric sol – gel process used in the preparation of composite inorganic membranes

A suspension is a dispersion of solid particles in a liquid; a sol is a suspension of colloidal particles or polymers. The main difference between suspension and sol is the size of the dispersed particles. Suspensions are prepared from a fine powder of aluminum oxide with an average particle diameter of 5 – 10 µm. The dispersion is mixed with an organic polymer such as poly(vinyl alcohol) or a cellulose derivative and poured in a mold or extruded in the desired shape as a flat sheet, tube, or capillary, dried, and sintered at 1500 – 1800°C. The process scheme is shown in Figure 48.

One surface of the support structure is then coated again with a suspension of finer particles, dried, and sintered again. Sometimes, more than one coating is applied to obtain the desired pore size at the surface of the membrane. The process of preparing a multilayer membrane by using suspensions of different particle sizes is referred to as slip coating. With the slip-coating process membranes with pore sizes down to 20 nm for use in microfiltration can be made. To obtain membranes with smaller pores a soll – gel process is applied and a colloidal or polymeric gel is used, which is prepared by controlled hydrolysis of a metal alkoxide to a hydroxide. The process can follow two different process paths. One path is referred to as the colloidal and the other the polymeric process path. Both pathways are illustrated in Figure 49.

In the colloidal process path a metal oxide such as aluminum oxide is dissolved in alcohol and then hydrolyzed and precipitated by addition of excess water at elevated temperature to form a stable colloidal solution. The solution is cooled to form a gel, which is then coated onto an appropriate support and sintered at about 800 °C. The average pore diameter obtained in the colloidal sol – gel process is in the range of 2 – 5 nm. The overall process consists of three steps:

Metal alkoxide formation: $Al_2O_3 + \text{alcohol} \longrightarrow Al(OR)_3$

Precipitation: $Al(OR)_3 + H_2O \longrightarrow Al(OH)_3 \longrightarrow \gamma\text{-}Al_2O_3 \cdot H_2O$

(Böhmite)

Coating and sintering: $\gamma\text{-}Al_2O_3 \cdot H_2O \longrightarrow \gamma\text{-}Al_2O_3$

In the polymeric sol – gel process the metal alkoxide is only partially hydrolyzed in an alcohol solution by a controlled addition of a minimum of water. The hydroxyl groups of the alkoxide react with each other and form an inorganic/organic polymer which forms a clear gel that is coated on the support structure. It is dried and sintered at 500 – 800 °C and further cross-linked to form a porous structure with a pore diameter of less than 1 nm. For the polymer sol – gel process often a titanium alkoxide is used which is converted into a cross-linked inorganic polymer in three steps:

- Hydrolysis of the metal alkoxide
- Polymerization and coating
- Sintering and cross-linking

5.1.6. *Preparation of Homogeneous Solid Membranes*

The selective barriers of many composite membranes can be considered as homogeneous solid membranes. In homogeneous solid membranes the entire membrane consists of a dense, solid, and pore-free structure. They are made from polymers and inorganic materials such as glass or metal. Because of their high selectivity for different chemical components, homogeneous membranes are used in various applications, which generally involve the separation of low molecular mass components with identical or nearly identical molecular dimensions. The most important applications are in gas separation.

One of the more important homogeneous solid metal membranes is the palladium or palladium alloy membrane used for the separation and purification of hydrogen [110]. The permeability of hydrogen in palladium, palladium alloys, and several other metals such as platinum, silver, and nickel is several orders of magnitude higher than that of any other gas. The permeability of hydrogen in palladium alloy membranes is highly temperature dependent, and separation is carried out at about 300 °C. Membranes generally consist of metal foils 10 – 50 µm thick. Because of their high selectivity, these membranes are used to produce high-purity hydrogen (> 99.99 %).

Homogeneous silica glass membranes are homogeneous structures that show promise as selective barriers for the separation of helium. Like metal membranes, glass membranes are employed at elevated temperature. Homogeneous glass membranes also have a high selectivity for hydrogen ions and are used as the selective barrier in pH electrodes. Their preparation is described in the literature [111].

5.1.7. *Preparation of Liquid Membranes*

Liquid membranes are important in combination with facilitated and coupled transport, which utilize selective “carriers” to transport certain components such as metal ions selectively and at a relatively high rate across the liquid membrane. Liquid membranes generally consist of a thin film separating two phases which may be aqueous solutions or gas mixtures. The material used for the liquid membrane should be immiscible with water and should have a low vapor pressure to guarantee long-term stability of the membrane. It is relatively easy to form a thin oil film between two aqueous or gas phases. It is difficult, however, to maintain and control this film and its properties during a mass separation process. Two different techniques are used today for the preparation of liquid membranes. In the first, which leads to supported membranes, the pores of a porous membrane are filled with the selective liquid barrier material (Fig. 50a). In the second, the liquid membrane is stabilized as a thin oil film by a surfactant in an emulsion-type mixture (Fig. 50b). In the supported liquid membranes, the porous structure provides the mechanical strength and the liquid-filled pores the selective separation barrier. Both types of membranes can be used for the selective removal of heavy-metal ions or certain organic components from industrial effluents [112, 114-116]. They have also been used rather effectively for the separation of oxygen and nitrogen [113].

Figure 50. Schematic of a) a supported hollow-fiber liquid membrane and b) the preparation of an emulsion-type liquid membrane

The preparation of supported liquid membranes is extremely simple. To maximize the useful lifetime of a membrane, the liquid membrane material should have low viscosity, low vapor pressure (i.e., high boiling point), and, when used in aqueous solutions, low water solubility. The porous substructure should have a high porosity and a pore size small enough to support the liquid membrane phase under hydrostatic pressure; the polymer of the substructure should be hydrophobic because most liquid membranes are used with aqueous feed solutions. In practice, liquid membranes are prepared by soaking a hydrophobic porous membrane made from polytetrafluorethylene such as Gore-Tex or from polyethylene such as Cellgard [117] in a hydrophobic liquid. The liquid may be a selective carrier such as an oxime or a tertiary or quaternary amine dissolved in kerosene. The disadvantage of supported membranes is their thickness, which is determined by the thickness of the porous support structure. The latter is in the range of 10 – 50 µm, that is, about 100 times thicker than the selective barrier of an asymmetric polymer membrane. Thus, the fluxes of supported liquid membranes can be low even when their permeabilities are high.

The preparation of the unsupported liquid membrane is more complex [118]. Here, two immiscible phases (i.e., the hydrophobic oil-type membrane phase and a water phase, often referred to as stripping solution) are mixed to form an emulsion of water droplets in a continuous oil phase, which is stabilized by addition of a surfactant. This emulsion is then added to the second aqueous phase (the feed solution), and the first emulsion forms droplets in the second aqueous phase. The overall result is the separation of two aqueous phases by an oil phase forming the liquid membrane. Ideally, droplets form in this process in which the aqueous phase is surrounded by a relatively thin hydrophobic phase, the membrane, which is surrounded by a second continuous aqueous phase. In reality, several aqueous droplets are found in a single hydrophobic droplet, as shown in Figure 50b, and the diffusion pathways become longer. With another aqueous solution, the component to be eliminated is supplied to the original emulsion and passes through the membrane into the internal solution.

5.1.8. *Preparation of Ion-Exchange Membranes*

Ion-exchange membranes consist of highly swollen gels carrying fixed positive or negative charges. The properties and preparation of ion-exchange membranes are closely related to those of ion-exchange resins. As with resins, there are many possible types with different polymer matrices and different functional groups to confer ion-exchange properties on the product. Although there are a number of inorganic ion-exchange materials, most of them based on zeolites and bentonites, these materials are rather unimportant in ion-exchange membranes and are not discussed further.

Cation-exchange membranes have negatively charged groups fixed to the polymer matrix, and anion-exchange membranes have positively charged groups fixed to the polymer matrix. In a cation-exchange membrane, the fixed anions are in equilibrium with mobile cations in the interstices of the polymer (Fig. 51).

Figure 51. Schematic of a cation-exchange membrane showing the polymer matrix with the negative fixed charges, the positive counterions, and the negative co-ions

This figure shows schematically the matrix of a cation-exchange membrane with fixed anions and mobile cations (counterions). In contrast, the mobile anions, known as co-ions, are more or less completely excluded from the polymer matrix because their electrical charge is identical to that of the fixed ions. Due to the exclusion of the co-ions, a cation-exchange membrane permits transfer of cations only. Anion-exchange membranes carry positive charges fixed on the polymer matrix. Therefore, they exclude all cations and are permeable only to anions. The most desired properties for ion-exchange membranes are:

- High permselectivity: an ion-exchange membrane should be highly permeable for counterions and impermeable to co-ions.
- Low electrical resistance: the permeability of an ion-exchange membrane for the counterions should be as high as possible.
- Good mechanical and dimensional stability: the membrane should be mechanically strong and have a low degree of swelling on transition from dilute to concentrated ionic solutions.
- High chemical stability: the membrane should be stable over a large pH range and in the presence of oxidizing agents.

It is often difficult to optimize the properties of ion-exchange membranes because the parameters determining the different properties often act contrary to one another. For instance, a high degree of crosslinking improves the mechanical strength of the membrane but also increases its electrical resistance. A high concentration of fixed ionic charges in the membrane matrix leads to a low electrical resistance but generally causes a high degree of swelling and poor mechanical stability. The properties of ion-exchange membranes are determined by two parameters, namely, the polymer matrix and the type and

concentration of the fixed ionic moieties. The polymer matrix largely determines the mechanical, chemical, and thermal stability of the membrane. Often it consists of a hydrophobic polymer such as polystyrene, polyethylene, or polysulfone. Although these polymers show a low degree of swelling in water, they become hydrophilic by the introduction of the ionic moieties, and swelling in water is strongly increased. Therefore, the polymer matrix of ion-exchange membranes is very often cross-linked. The degree of cross-linking then largely determines the degree of swelling and the chemical and thermal stability, but it also has a large effect on the electrical resistance and the permselectivity of the membrane. The type and the concentration of the fixed ionic charges determine the permselectivity and the electrical resistance of the membrane, but they also have a significant effect on the mechanical properties. The degree of swelling especially is affected by the concentration of the fixed charges. The following moieties are used as fixed charges in cation-exchange membranes:

$$-SO_3^- \quad -COO^- \quad -PO_3^{2-} \quad -PHO_2^- \quad -AsO_3^{2-} \quad -SeO_3^-.$$

In anion-exchange membranes fixed charges may be:

$$-\overset{+}{N}H_2R, \quad -\overset{+}{N}HR_2, \quad -\overset{+}{N}R_3, \quad -\overset{+}{P}R_3, \quad -\overset{+}{S}R_2.$$

The sulfo group is completely dissociated over nearly the entire pH range, whereas the carboxyl group is virtually not dissociated below a pH value of 6. The quaternary ammonium group is completely dissociated at all pH values, whereas the primary ammonium group is only weakly dissociated. Accordingly, ion-exchange membranes are referred to as being weakly or strongly acidic or basic in character. Most commercial ion-exchange membranes are either homogeneous or heterogeneous. In homogeneous membranes the ion-exchange groups are homogeneously distributed throughout the polymer, whereas in heterogeneous membranes the ion-exchange particles are dispersed in a neutral polymer matrix. In general, heterogeneous membranes have a relatively high electrical resistance. Homogeneous ion-exchange membranes have a more even distribution of fixed ions and often a lower electrical resistance.

The preparation of ion-exchange membranes is described in a large number of detailed recipes in the literature [119-126]. For the practical preparation of ion-exchange membranes two rather different procedures are used. A quite simple technique is based on mixing an ion-exchange resin and a binder polymer such as poly(vinyl chloride) and extruding the mixture as a film at a temperature above the melting point of the polymer. The result is a heterogeneous membrane with relatively large domains of ion-exchange material and no conductive regions of the binder polymer. To obtain ion-exchange membranes with satisfactory conductivity the fraction of ion-exchange resin must be in excess of 50 – 70 wt %. This often leads to rather high swelling and to poor mechanical stability of the membrane. Furthermore, the size of the ion-exchange particles should be as small as possible (i.e., < 2 to 20 µm in diameter) to be able to make thin membranes with low electrical resistance and high permselectivity. Nevertheless, the method is still used today on a large scale for the preparation of ion-exchange membranes.

More recently homogeneous ion-exchange membranes have been produced by polymerization of monomers that carry anionic or cationic moieties or by introducing these moieties into a polymer which may be in an appropriate solution or a preformed film.

A typical example for the preparation of an ion-exchange membrane by polymerization and sulfonation of monomers is the polymerization of styrene with divinylbenzene and subsequent sulfonation according to the following reaction scheme:

For the preparation of anion-exchange membranes positively charged groups are introduced into the polystyrene by chloromethylation and amination with triamine according to the following reaction scheme:

Cation-exchange membranes with good overall properties can be made by sulfonation of polyetherketone according to the following reaction scheme:

Anion-exchange membranes with excellent chemical stability can be prepared by incorporating the monoquaternary salt of 4,4′-diazabicyclo[2.2.2]octane into a chlormethylated polysulfone matrix giving an anion-exchange membrane of the following structure:

Both the cation- and the anion-exchange membrane have excellent chemical and mechanical stability and good electrochemical properties [72].

In the literature, there are numerous methods reported for the preparation of ion-exchange membranes with special properties, for instance, for use as battery separators, ion-selective electrodes, or in the chlor-alkali process. Especially membranes for the chlor-alkali industry are of commercial significance. These membranes are based on polytetrafluoroethylene and carry sulfone groups in the bulk of the membrane phase and carboxyl groups on the surface as the charged moiety. They combine excellent chemical stability with high selectivity and low electrical resistance. Today's commercially available perfluorocarbon membranes have the following basic structure:

$k = 5\text{-}8$, $l = 600\text{-}1200$, $m = 1\text{-}2$, $n = 1\text{-}4$, $X = SO_3^-, COO^-$

The synthesis of the perfluorocarbon membranes is rather complex and requires a multistep process [124]. Perfluorinated membranes have excellent chemical and thermal stability. Their lifetimes under the aggressive conditions of the chlor-alkali

process are on the order of three years.

Other special-property membranes were developed for the production of table salt [127] and for use in diffusion [128] and Donnan dialysis. Significant effort has been also been concentrated on the development of anion-exchange membranes with low fouling tendencies [129] and low proton permeability [130].

A significant effort has been concentrated on the development of bipolar membranes, which have recently gained increasing attention as an efficient tool for the production of acids and bases from their corresponding salts by accelerated water dissociation. Bipolar membranes can be prepared by simply laminating conventional cation- and anion-exchange membranes back to back [131]. Laminated bipolar membranes often exhibit unsatisfactory water splitting capability. Special surface treatment of commercial ion-exchange membranes and subsequent laminating may yield bipolar membranes with satisfactory properties. Single-film bipolar membranes and multilayer bipolar membranes fulfill most of the practical needs [132].

5.2. Membrane Characterization

Membrane characterization is a very important part of membrane research and development because the design of membrane processes and systems depends on reliable data relating to membrane properties. To select a membrane to be used in a particular separation process its properties must be known. Since membranes are very different in their properties and applications a large number of different techniques are required for their characterization. Some of the more important membrane characterization procedures described in the literature or recommended by membrane manufacturers are briefly reviewed here.

5.2.1. *Characterization of Porous Membranes*

Porous micro- or ultrafiltration membranes are generally characterized in terms of their flux, their pore size, their pore size distribution, and their molecular mass cutoff. Other important characteristics are the nature of the membrane material (whether it is hydrophilic or hydrophobic or carrying positive or negative charges), the structure of the membrane (whether it is symmetric or asymmetric) and their mechanical, chemical, and thermal stability. The methods used to characterize porous membranes include simple filtration and retention measurements, microscopic techniques, surface tension measurements, and the determination of pore radii by liquid – gas or liquid – liquid replacement. The chemical and mechanical stability at various temperatures is usually measured in long-term tests. Which of the membrane characterization methods are applied depends on the anticipated use of the membrane.

Pure-Water Flux of Micro- and Ultrafiltration Membranes. A characteristic property of micro- and ultrafiltration membranes is their pure-water flux or pure-water permeability. The flux J through a porous medium is proportional to the applied hydrostatic pressure and inversely proportional to the solvent viscosity. It is expressed in Darcy's law:

$$J_v = \frac{L_p \Delta p}{\eta} \tag{5.2}$$

where J_v is the membrane flux, L_p the hydrodynamic solvent permeability, η the viscosity of the solution passing through the pores of the membrane, and Δp the applied pressure.

For the determination of the pure-water flux it is very important to use a certain water quality. Generally de-ionized or distilled water with a conductivity of less than 5 µS/cm^{-1} which has been treated by microfiltration to remove suspended materials is used as test solution. The flux is determined at different applied pressures and plotted as a function of the pressure. From the slope of the plot the hydrodynamic permeability is obtained. Prior to the flux measurements the membranes should be pressurized by filtration of pure water at a hydrostatic pressure that is at the upper limit of the recommended operating pressure for 1 – 2 h to compress the membrane to a stable state that will not further deform when used at lower pressures. Preservatives, which are often present in membranes, must be eliminated by a washing procedure.

Some inorganic membranes, like Al_2O_3-based types, show an apparent internal pore clogging when de-ionized water is used in pure-water flux measurements. In these cases an electrolyte solution is used for determining the membrane flux (e.g., an NaCl or KCl solution). Since there is no standard method for the determination of the pure-water flux, companies use their own standards, which makes a reliable comparison of pure-water fluxes rather difficult. Typical pure-water fluxes of microfiltration membranes vary from 500 to 50 000 L m^{-2} h^{-1} bar^{-1}, while those of ultrafiltration membranes vary from 50 to 800 L m^{-2} h^{-1} bar^{-1}.

In practical applications fluxes are normally much lower and a steep flux decline is observed during the first period of operation, mainly due to membrane fouling, which is generally more pronounced for microfiltration than for ultrafiltration. More details on membrane fouling are given in Section Membrane Fouling and its Causes.

Microscopic Techniques. A variety of microscopic techniques are used to study membrane structures, such as scanning electron microscopy, field emission electron microscopy, transmission electron microscopy, and atomic force microscopy. The advantage of these techniques is that direct visual information of the membrane morphology is obtained. The different microscopic techniques require different preparation methods and have different resolutions. Scanning electron microscopy, for example, has a resolution of up to 5 nm and provides good information on the structures of micro- and ultrafiltration membranes including pore sizes and pore shapes. To reach a high resolution high electron-beam energy has to be applied, which can damage the membrane samples. Another problem is that in electron microscopy the samples must be coated by a conductive layer. This is generally done in a high vacuum which can lead to a change in the structure of membranes made from hydrophilic polymers.

The pore sizes and pore shapes of ultrafiltration membranes can also be determined by transmission electron microscopy, which has a resolution of 0.4 – 0.5 nm, or by field emission electron microscopy, which has a resolution of 0.6 – 0.7 nm.

Transmission electron microscopy requires a significantly more complex preparation procedure and is mainly applied to determine the surface porosity of ultrafiltration membranes [133]. Because of the high resolution, pores in ultrafiltration membranes can be visualized by field emission electron microscopy [134].

Sample preparation for scanning electron microscopy and field emission electron microscopy is relatively easy compared to that for transmission electron microscopy. To visualize the cross sections of a membrane, for example, it is immersed in ethanol or a water – ethanol mixture prior to cooling in liquid nitrogen. The sample is fractured to give a rather clean fracture and glued with a conductive glue to a sample holder and sputtered with a thin layer of gold. The sputtered layer should be thinner than the structural features of the membrane to be studied. More recently, low-vacuum scanning electron microscopy (so-called environmental scanning electron microscopy) has become available, which makes it possible to scan samples without a conductive coating. However, the magnification of these microscopes is limited to 7500. Figures 40 to 42 show typical pictures of membrane structures that can be obtained by scanning electron microscopy.

Besides electron microscopy, atomic force microscopy is also applied to study membrane surface structures. It has a resolution of about 1 nm [135]. Sample preparation is fairly simple, since no conductive coating is required. Therefore, samples need not be dried and exposed to vacuum.

5.2.1.1. *Membrane Separation Properties Determined by Filtration Tests*

Both micro- and ultrafiltration are pressure-driven membrane processes using porous membranes. The separation of various components is based on a sieving mechanism in which particles or molecules which are larger than the pores of a membrane are retained by the membrane. The membrane retention as a function of the particle size and the pore size can be defined by a relation between the pore and the particle radius [136]. If the particles are spherical and have a radius r_s and the membrane pores are cylindrical with a radius r_p the following relation can be used to describe the membrane solute rejection:

$$R = \left[1 - \left(1 - \frac{r_s}{r_p}\right)^2\right]^2 \tag{5.3}$$

For the radius of the molecule either the radius of gyration or the hydrodynamic radius can be used. The so-called Ferry model [136] is rather simplified, but gives a good approximation of the expected retention when particle size and the membrane pore radius are known.

Retention and Molecular Weight Cutoff. To describe the retention of ultrafiltration membranes usually the molecular weight cutoff is used. Determination of the molecular weight cutoff is very sensitive to the experimental conditions, that is, the solutes and their concentration used in the test, the applied pressure, and the temperature. Therefore, a comparison of retention data given by different manufacturers is generally problematic. As test conditions for determining the ultrafiltration membrane cutoff a transmembrane pressure of 100 kPa, a feed solution concentration of 0.1 %, and a test temperature of 25 °C are recommended. Furthermore, maximum agitation of the feed solution at the membrane surface is required to minimize concentration polarization effects, and small amounts of solution should be filtered to assure a constant feed concentration.

The retention is generally expressed in per cent and defined by:

$$R = \left(1 - \frac{C_p}{C_f}\right)100 \tag{5.4}$$

where R is the retention or rejection of a membrane, and C_f and C_p are feed and permeate concentration.

The retention of molecules having identical molecular weights may be rather different when their shape is different. Globular proteins, for example, are rejected more easily than branched polysaccharides or flexible polymers [137]. Adsorption of the solute on the membrane surface, for example, may result in high “apparent” retention values when the experiment is performed for a very short time period. Accumulation of solutes at the membrane surface due to concentration polarization effects can also obscure the retention measurements and must be considered when the true (i.e., intrinsic) retention is to be determined. These effects can more or less be eliminated by using low pressures, low feed concentrations, and a high degree of agitation.

Manufactures of ultrafiltration membranes generally use marker molecules such as dextrans and proteins for the determination of the molecular weight cutoff of their membranes. In addition, the sharpness of the cutoff is important for practical applications. It is determined by measuring the retention of the membrane for components of different molecular weight and plotting the retention versus the molecular weight of the retained components (Fig. 52). The figure shows the characteristic curves of a membrane with sharp and diffuse cutoff. The sharpness of the cutoff of a membrane depends mainly on its pore size distribution. For practical applications the cutoff should be as sharp as possible.

Figure 52. Schematic illustrating membrane cutoff characteristics

Bacterial Challenge Test. Micro- and ultrafiltration membranes are often used in the food and pharmaceutical industry for the sterilization of solutions. In this application it is important that membranes retain undesired microorganisms as completely as possible. Therefore, these membranes are subjected to a bacterial challenge test with a solution containing a minimum

concentration of organisms such as *Pseudomonas diminuta* per cubic centimeter of solution [138]. The data obtained in bacterial challenge tests are normally expressed in terms of the logarithmic reduction value, which is given by the logarithm of the ratio of feed to filtrate concentration. The bacterial challenge test is a destructive test and is therefore not suited as an on-line quality-control test. For this application the nondestructive diffusion and the bubble-point integrity tests are generally applied.

Membrane Pore Size Measurement. In addition to filtration tests micro- and ultrafiltration membranes are characterized by determining their pore size and pore size distribution by a number of techniques such as liquid – gas and liquid – liquid displacement, mercury intrusion, permporosimetry, thermoporosimetry, and the bubble point test.

The *bubble point test* is a structural integrity test in which the largest pore or hole in a membrane is determined. The bubble point method is based on the capillary effect of small pores due to surface tension forces. In equilibrium these forces are balanced with gravity of the liquid in the pores. The principle is shown in Figure 53.

Figure 53. Schematic illustrating the capillary effect of a membrane pore

This equilibrium between surface tension forces and gravity of the liquid in the pore can be expressed by the following equation:

$$2\pi\, r_p \sigma \cos\, \varphi = r_p^2 \pi\, h \rho g \tag{5.5}$$

where r_p is the pore radius, σ the surface tension of the liquid in contact with air, cos φ the contact angle between the liquid and the wall of the pore, h the height of the liquid column, ρ the liquid density, and g the acceleration due to gravity.

The term $h\,\rho g$ in Equation 5.5 can be replaced by the pressure p to give the LaPlace equation:

$$r_p = \frac{2\sigma \cos \varphi}{p} \tag{5.6}$$

The bubble point method is a fairly simple technique where the pores of a membrane are filled with a liquid. From the bottom side of the membrane nitrogen gas or air is introduced with increasing pressure. At a certain pressure the gas will replace liquid in the largest pores permeating the membrane, and a bubble rising from the membrane surface can be observed. Equation 5.6 gives a relation for the surface tension between the liquid and the gas and the required pressure to open up pores of a certain size. In the bubble point test mostly water or isopropyl alcohol is used, since the surface tension of water – air is approximately 3.5 times higher than that of isopropyl alcohol – air. Other techniques to determine the pore size and pore size distribution of a porous membrane that are also based on the La Place equation, but cover different pore size ranges when the same pressure range is applied, are mercury porosimetry, gas – liquid displacement, and liquid – liquid displacement.

In *mercury porosimetry* a dry membrane is exposed to a certain volume of liquid mercury. The pressure applied to the mercury is slowly increased, while simultaneously the amount of mercury forced into the porous structure is measured. The largest pores are filled first and the required pressure for the mercury to penetrate the porous structure increases with decreasing pore size. The required pressure corresponds to a certain pore radius and the amount of mercury that enters the membrane corresponds to the total volume of these pores. The interfacial tension of mercury and air is very high. Therefore, relatively high pressures are required to fill small pores. In polymer membranes only pores having a radius in excess of 1 µm can be detected reliably by mercury porosimetry. Furthermore, this technique does not distinct between dead-end pores and interconnected pores.

The *gas-liquid displacement technique* is identical to the bubble point method. The pores of the membrane are generally filled with an organic solvent which has a lower surface tension than water. The solvent is forced out of the membrane pores by nitrogen gas, which is introduced with increasing pressure. As the pressure increases the liquid is replaced by nitrogen in the largest pores first and a convective gas flow through these pores occurs. The gas flow is measured as a function of the applied pressure. When all the pores are opened a linear relationship between pressure and gas flow is observed when the pressure is further increased. Figure 54 shows schematically typical gas fluxes obtained as a function of pressure with a dry and a liquid-filled membrane.

Figure 54. Schematic illustrating gas – liquid displacement measurements to determine the pore size and pore size distribution of microfiltration membranes

The mean flow pore size is given by the point where the 50 % dry-flow curve crosses the wet-flow curve. The maximum pore size is given by the point at which flow through the liquid filled membrane is first observed. The minimum pore size is given by the point where the fluxes of the dry and the liquid-filled membrane become identical. The LaPlace equation (Eq. 5.6) describes the relationship between the pore radius and the applied pressure.

Liquid – liquid displacement differs from gas – liquid displacement in that the liquid in the pores is displaced by a second liquid instead of a gas. The two liquids applied should be immiscible. A typical liquid pair used is water – isobutanol. Both liquids are first saturated with each other before one of them is used to fill the pores and the other liquid is applied as displacement liquid. The experimental setup for the determination of pore sizes by liquid – liquid displacement is shown in Figure 55. A slow increase in the displacement liquid pressure pushes the liquid out of the largest pores first. With increasing pressure the liquid in the smaller pores is also replaced. The pore size distribution can be calculated from a plot of the flux versus the applied pressure [139, 140].

Whether isobutanol or water is used as displacing liquid depends on the nature of the membrane material. Due to swelling phenomena different results might be obtained dependent on the liquid occupying the pores.

Figure 55. Schematic of a typical liquid – liquid displacement setup [139]

The relation between the pore radius and the pressure required to open pores of a certain size is again described by the LaPlace equation (Eq. 5.6) and the pore size distribution can now be calculated by measuring the flux as a function of the pressure. Like in gas – liquid displacement only active pores contributing to transport are taken into account. Pore diameters of approximately 5 – 100 nm can be analysed by liquid – liquid displacement. The advantage of liquid – liquid displacement over gas – liquid displacement is the lower interfacial tension between two liquids compared to a gas – liquid combination. Therefore, pores of the same size can be opened at much lower pressures in liquid – liquid displacement.

Other methods that can be used to determine pore sizes in porous membranes [141, 142] include permporometry and thermoporometry. *Permporometry* is a technique based on gas adsorption – desorption measurements in which pores are either filled by controlled condensation of a vapor phase or filled pores are emptied by controlled evaporation of the liquid inside the pores. The relation between the relative vapor pressure and the pore radius is given by the Kelvin equation. *Thermoporometry* is based on the microcalorimetric analysis of a solid – liquid transition by sensitive differential scanning calorimetry. Table 4 lists the pressures required to open pores of 10 nm for different displacement systems. An advantage is that membranes are characterized in a wetted state and therefore the test conditions are closer to the real operating conditions.

Table 4. Different porosimetry techniques and the influence of interfacial tension on the pressure required to open pores of 10 nm

Technique	System	Interfacial tension, mN m^{-1}	Pressure, bar
Mercury porosimetry	air/mercury	480	749
Bubble point	air/water	72.3	145
Coulter porometry	air/Porofil	16	32
Gas – liquid displacement	air/isobutanol	20.7	41
Liquid – liquid displacement	water/isobutanol	1.85	3.7
Liquid – liquid displacement	water/isobutanol/methanol	0.35	0.7

5.2.2. *Characterization of Homogeneous Membranes*

Homogeneous membranes are generally used for the separation of low molecular mass materials such as gases, salts, or solvents. The transport mechanism in these membranes is based on the solution and diffusion of components within the membrane matrix. The intrinsic properties of the membrane material are often more relevant for characterizing their transport behavior than is the macroscopic membrane structure. Characterization methods used with microporous structures have therefore been supplemented with other procedures, such as sorption and diffusion measurements or determination of the glass transition temperature and crystallinity of the membrane material. For ion-exchange membranes, the measurement of electrokinetic properties is required.

A detailed discussion of all methods used to characterize *homogeneous polymer membranes* is beyond the scope of this outline. In addition to the determination of diffusion and partition (solubility) coefficients, measurements providing information on the physical structure of the polymer, such as differential scanning calorimetry, X-ray studies, or determination of the free volume in a polymer, are important. These methods are described in [143, 145, 146]. Permeability and selectivity are the most interesting parameters; they are determined in permeation tests and expressed in terms of rejection coefficients (in reverse osmosis) or separation coefficients (in gas separation and pervaporation). These coefficients are usually not constant but a function of composition, temperature, and pressure. Furthermore, the determination of membrane fluxes and selectivities in practical measurements is often obscured by boundary layer effects at the membrane surface.

The methods used to determine the structural properties of *ion-exchange membranes* are similar to those used for characterizing other polymer membranes. Because ion-exchange membranes are used mainly in separation processes with electrical potential driving forces, their permeability and selectivity are determined under experimental conditions closely

related to their practical use, and their properties are expressed in terms commonly used in electrochemistry (e.g., electrical resistance, ion-transfer numbers, charge densities) [72].

5.3. Membrane Modules

To use a membrane in a separation process it must be installed in a proper device which is generally referred to as a membrane module. Membrane modules must meet certain requirements with regard to production costs, packing density, energy consumption, and control of concentration polarization. The modules used in the practical applications of membrane separation processes are quite different [147-149]. In small-scale laboratory applications often stirred batch cells or dead-end filter cells are used. In large-scale industrial applications six basic module types are used. These modules are shown schematically in Figures 56 to 61. They are quite different in their design, their mode of operation, their production costs, and the energy requirements for pumping a feed solution through the module. Commercially available modules, even if they are of the same type, can vary significantly in detail and are often tailor-made for a certain application. Here, only the basic concepts of the different module types are discussed.

In some modules, for example, tubular, plate-and-frame, and capillary type modules, concentration polarization and membrane fouling can effectively be controlled by proper feed flow. Other modules such as the spiral-wound and the hollow-fiber module are more sensitive to membrane fouling. There is no module type that serves all membrane processes and applications. The different modules which are commercially available today are designed for a certain application and process in which they provide the technically and commercially best solution. The same is true for the process design and mode of operation. In certain applications batch and feed-and-bleed operation is used, while in others continuous operation is more efficient.

5.3.1. *Cartridge Membrane Module*

The pleated cartridge filter membrane module (Fig. 56) is used mainly in dead-end microfiltration. It consists of a pleated membrane cartridge installed in a pressurized housing. The feed solution enters the filter from the housing side and the product is collected in a center tube which is sealed against the housing by an O-ring. Cartridge filters are operated at relatively low hydrostatic pressures of 1 – 2 bar. Their useful life is limited due to plugging of the membrane pores by the retained solutes.

Figure 56. Schematic of a cartridge filter unit

The useful life of a cartridge filter depends very much on the feed solution constituents and their concentration. It can vary between a couple of days and several months. Cartridge filters are disposable items. If the membrane, which has the typical characteristics of a depth filter, is blocked by the retained particles it can generally not be cleaned and the original flux cannot be restored. The main application of cartridge filters is in sterile filtration of water, beverages such as wine, beer, and fruit juices, and pharmaceutical solutions. They are also used for the filtration of surface water for industrial or household use to remove particles and suspended matter and to serve as prefilters in reverse-osmosis water-desalination plants. An important application of cartridge filters is in the production of ultrapure water for the electronic industry, where they are used as point-of-use filters to remove all traces of particles from the ultrapure water used to rinse electronic components. The actual cartridge is made by pleating a membrane sheet and potting the ends by an appropriate resin or hot-melt adhesive. Since the process of pleating the membrane places a considerable mechanical stress on the membrane, only materials that are rather flexible and have a certain mechanical strength are suited for the fabrication of cartridge filters. The cartridge filter module provides a relatively high surface area per unit volume and the production costs are relatively low.

5.3.2. *Plate-and-Frame Membrane Module*

Another module type used on an industrial scale for various membrane separation processes including ultrafiltration, reverse osmosis, and gas separation is the plate-and-frame module. Its design has its origin in the conventional filter press concept. The membranes, porous membrane support plates, and spacers forming the feed flow channel are clamped together and stacked between two endplates and placed in a housing (Fig. 57).

Figure 57. Schematic illustrating a) the concept of a plate-and-frame membrane module and b) a circular plate-and-frame filter device with one baffle to extend the feed flow path length

The feed solution is pressurized in the housing and forced across the surface of the membrane. The permeate leaves the module through the permeate channel to a permeate collection manifold, which in circular devices is a central tube, as shown in Figure 57b. Often the device contains one or more baffles to extend the path length of the feed solution in the device. There are various types of plate-and-frame modules on the market, but they offer only slight variations in their basic

configuration. In many plate-and-frame membrane modules the membranes can easily be exchanged. This makes the module suitable for batch-type operations and multipurpose applications using different membranes for different separation tasks. Plate-and-frame units are mainly used in small-scale applications such as the production of certain pharmaceuticals, bioproducts, or fine chemicals. The housings and other components of plate-and-frame modules to be used in the food and pharma industry are made from stainless steel so that they can easily be steam-sterilized. These units, however, are quite expensive and the exchange of the membranes is labor-intensive. Therefore, the plate-and-frame module is quite expensive. However, one exception is the electrodialysis stack, which resembles a plate-and-frame unit in which cation- and anion-exchange membranes are stacked in alternating series between two end plates. A typical sheet-flow electrodialysis stack is shown in Figure 58.

Figure 58. Arrangement of cation- and anion-exchange membranes in an electrodialysis stack

This device holds an array of membranes between electrodes in such a way that the streams being processed are kept separate. Gaskets between the membranes form the individual cells and contain manifolds to distribute the process fluids in the different compartments. The distance between the membrane sheets in industrial-size electrodialysis stacks is typically between 0.5 and 2 mm. In a practical electrodialysis system 200 – 1000 cation- and anion-exchange membranes are installed in parallel between two electrodes, and a stack contains 200 – 1000 m^2 of membrane area. Thus, the membrane area per unit volume is relatively high. The electrodialysis stack is discussed in Section Membrane Separation Process Design and Operation.

5.3.3. *Spiral-Wound Module*

A variation of the basic plate-and-frame concept is the spiral-wound module, which is widely used today in reverse osmosis, ultrafiltration, and gas separation. Its basic design is illustrated in Figure 59.

Figure 59. Schematic of a spiral-wound membrane module

The feed flow channel spacer, the membrane, and the porous membrane support form an envelope which is rolled around a perforated central collection tube and inserted into an outer tubular pressure shell. The feed solution passes in axial direction through the feed channel across the membrane surface. The filtrate is moved along the permeate channel and is collected in a perforated tube in the center of the roll. Small spiral wound units consist of just one envelope which limits the total membrane area that can be installed in one unit to about 1 – 2 m^2. The main reason for the limitation of the surface area which can be installed in a module containing one single envelope is the pressure drop encountered by the permeate moving down the permeate channel to the central collection tube. Because the channel in a practical unit is very narrow its length is limited to 2 – 5 m. A significantly longer path would result in an unacceptable pressure drop in the permeate channel. To install larger membrane surfaces in a spiral-wound module and to extend the path of the permeate a multileaf arrangement is used. Commercial spiral wound modules are about 1 m long and have a diameter of 10 – 60 cm. The membrane area in a spiral-wound element is 3 – 60 m^2. Generally, 2 – 6 elements are placed in series in a pressure vessel.

The spiral-wound module provides a relatively large membrane area per unit volume. Large-scale production is quite cost effective and module costs per membrane area are quite low. The major application of the spiral-wound module is in desalination of sea- and brackish water by reverse osmosis, but it is also extensively used in ultrafiltration and gas separation. However, the spiral-wound module is quite sensitive to fouling, and the feed channels can easily be blocked, so particles or fibers should be removed from the feed solution by a proper pretreatment procedure.

5.3.4. *Tubular Membrane Module*

While the previously described three membrane module types require flat sheet membrane material for their preparation, special membrane configurations are needed for the preparation of tubular, capillary, and hollow-fiber modules.

The tubular membrane module consists of membrane tubes placed into porous stainless steel or fiber glass reinforced plastic pipes. The pressurized feed solution flows down the tube bore and the permeate is collected on the outer side of the porous support pipe, as indicated in Figure 60a. The diameters of tubular membranes are typically between 1 and 2.5 cm. In some modules, the membranes are cast directly on the porous pipes, and in others they are prepared separately as tubes and then installed into the support pipes. Today, tubular modules are used in ultrafiltration at low hydrostatic pressures. This allows the membrane tubes to be made by welding or gluing of flat sheet membranes that are cast on a relatively thick and mechanically strong porous polyester support material. These tubes, which have a diameter of 0.5 – 1 cm, do not need additional support when operated at hydrostatic pressures of less than 2 – 4 bar.

Usually, 10 – 30 individual tubes are installed in a larger tube and potted at the end of the tube. The feed solution is fed in parallel through the tubular bundle while the permeate of the individual tubes is collected in the outer shell tube, as shown in Figure 60b. The main advantage of the tubular module is that concentration polarization effects and membrane fouling can be easily controlled, and plugging of the membrane module is avoided even with feed solutions that have very high concentrations of solid matter and thus high viscosity. The disadvantage of the tubular module is the low surface area that can be installed in a given unit volume and the very high cost. Therefore, tubular membrane modules are generally only applied in applications where feed solutions with high solids content and high viscosity must be treated and other module

concepts fail due to membrane fouling and module plugging. This is the case in certain applications in the food and pharmaceuticals industries and in the treatment of certain industrial effluents.

Figure 60. Schematic illustrating the tubular membrane module a) with individual tubes in series and b) with seven individual tubes in parallel bundled in a shell tube

5.3.5. *Capillary and Hollow-Fiber Membrane Modules*

The capillary membrane module (Fig. 61a) consists of a large number of membrane capillaries with an inner diameter of 0.2 – 3 mm arranged in parallel as a bundle in a shell tube. The feed solution is passed down the center of the membrane capillary, and the filtrate, which permeates the capillary wall, is collected in the shell tube. The capillary membrane module requires membranes in a self-supporting capillary configuration, which when asymmetrically structured, carry the selective barrier on the inner side of the capillary, as indicated in Figure 42b, which shows a typical capillary, ultrafiltration membrane prepared in a wet-spinning process.

Figure 61. Schematic illustrating the construction a) of a capillary module and b) of a hollow-fiber module

The same basic spinning process is used for the preparation of hollow-fiber membranes, which have an outer diameter of 50 – 100 µm. In hollow-fiber membranes, the selective layer is on the outside of the fibers, which are installed as a bundle of several thousand fibers in a half loop with the free ends potted with an epoxy resin in a pressure tube, as shown in Figure 61b. The filtrate passes through the fiber walls and flows up the bore to the open end of the fibers at the epoxy head.

The hollow-fiber membrane module has the highest packing density of all module types available on the market today and its production is very cost effective. Hollow-fiber membrane modules can be operated at pressures in excess of 100 bar. The main disadvantage of the hollow-fiber membrane module is the difficult control of concentration polarization and membrane fouling. When operated with liquid solutions the modules do not tolerate any particles, macromolecules, or other materials that can easily precipitate at the membrane surface. Therefore, an extensive pretreatment is required when hollow-fiber membranes are used for the treatment of liquid mixtures. The main application of the hollow-fiber module is in reverse osmosis desalination of seawater and in gas separation. Both applications require high operating pressures and low-cost membranes which have a long useful life. In reverse osmosis of seawater extensive pretreatment of the feed water is required.

5.3.6. *Other Membrane Modules*

Other membrane module concepts include the rotating-disk module, in which the membranes are arranged as in the circular plate-and-frame module. However, the feed solution is not pumped through the module but the membrane plates rotate and thus provide some turbulence in the feed solution at the membrane surface. This module is rather costly per unit installed membrane area and is used only in very specific applications in the pharmaceutical industry when solutions with very shear sensitive constituents must be processed.

Table 5 lists the different membrane modules, their costs per unit membrane area, and main applications.

Table 5. Commercially available membrane modules, their costs, and their applications

Membrane module	Membrane area per unit volume, $m^2\ m^{-3}$	Membrane costs	Control of concentration polarization	Applications[a]
Filter cartridge	800 – 1000	low	very poor	dead-end MF
Plate-and-frame	400 – 800	medium	good	MF, UF, RO, D, ED
Spiral-wound	800 – 1200	low	good	UF, RO, GS
Tubular	20 – 100	very high	very good	MF, UF, RO
Capillary	600 – 1200	low	very good	UF, MF, D, SLM
Hollow-fiber	2000 – 5000	very low	very poor	RO, GS

[a]D = dialysis, ED = electrodialysis, GS = gas separation, MF = microfiltration, RO = reverse osmosis, SLM = supported liquid membrane, UF = ultrafiltration.

6. Concentration Polarization and Membrane Fouling

Even if the proper membrane for a certain mass separation task is available, various engineering aspects must be considered that can affect the economics of the process considerably, or even make it technically impossible. A major problem in all membrane separation processes is the decline of the membrane flux due to concentration polarization effects and the formation of cake or gel layers by feed solution constituents retained by the membrane. Equally devastating for the performance of a process is membrane fouling. Membrane fouling is a more general term. It may be the result of concentration polarization, or the consequence of adsorption of feed solution constituents at the membrane surface and, especially in microfiltration, also within the membrane structure. The control of concentration polarization and membrane fouling is a major problem in the design of membrane separation processes and equipment [150-152].

Concentration polarization occurs in all separation processes, but its consequences are especially severe in membrane processes. When in a mass separation procedure a molecular mixture is brought to a membrane surface, some components permeate the membrane under a given driving force while others are retained. This leads to accumulation of retained material and depletion of the permeating components in the boundary layers adjacent to the membrane surface. This phenomenon is referred to as concentration polarization. The causes and consequences of concentration polarization may differ in different membrane processes. Often the adverse effects of concentration polarization are intensified by adsorption of certain feed mixture constituents at the membrane surface. This phenomenon is referred to as membrane fouling. It is often observed when solutions containing biological materials such as proteins are processed, but inorganic materials, especially polyelectrolytes, can also cause severe fouling. In biofouling microorganisms accumulate at and attach to the membrane surface. The actual mechanism of biofouling is rather complex and involves the formation of a so-called conditioning film, which consists of organic polymeric material that then leaves the membrane surface within the biocompatible range for attachment of film-forming bacteria. Biofouling is especially severe in reverse osmosis of seawater and its control is crucial for the reliable operation of reverse osmosis desalination plants. Concentration polarization can be minimized by hydrodynamic means such as the feed flow velocity and the membrane module design. The control of membrane fouling, however, is more difficult. Membrane fouling is influenced by the chemical nature of the membrane material and the feed solution constituents. To avoid or control membrane fouling extensive feed water pretreatment and dosage of special chemicals may be required. The causes and consequences of concentration polarization and membrane fouling as well as necessary means to control them depend on the feed water composition and on the membrane process.

6.1. Concentration Polarization in Filtration Processes

The causes and consequences of concentration polarization in pressure-driven membrane processes such as reverse osmosis and ultra- and microfiltration have been studied extensively [153-155]. While the causes for concentration polarization are identical in all three processes the consequences are rather different. When water selectively permeates a reverse osmosis or ultra- and microfiltration membrane, the retained solutes are accumulated at the membrane – solution interface. Thus, a concentration gradient between the solution at the membrane surface and the bulk is established which leads to backtransport of the material accumulated at the membrane by diffusion and eventually other means. This phenomenon is referred to as concentration polarization. In reverse osmosis mainly low molecular weight materials are separated from a solvent such as water. The feed solutions often have a considerable osmotic pressure. For example seawater has an osmotic pressure of about 24 bar. In reverse osmosis concentration polarization leads to an increase in the osmotic pressure, which is directly proportional to the solute concentration at the membrane surface, and thus a decrease in the membrane flux at constant applied hydrostatic pressure. Furthermore, the quality of the filtrate is impaired since solute leakage through the membrane is also directly proportional to the solute concentration at membrane feed-side surface [156, 157].

In ultra- and microfiltration only macromolecules and particles are retained by the membrane. The osmotic pressure of the feed solution is generally quite low. However, the applied hydrostatic pressure is also low and in certain applications of ultrafiltration the osmotic pressure can not be neglected. Due to the rather high molecular weight of the components separated in ultra- and microfiltration their diffusion from the membrane surface back into the bulk solution is relatively slow. Therefore, the retained components often are precipitated and form a solid layer at the membrane surface [158]. This layer, which often exhibits membrane properties itself, can effect the membrane separation characteristics significantly by reducing the membrane flux and by changing the rejection of lower molecular weight components. This is especially problematic in the fractionation of materials of different molecular weight.

To describe concentration polarization in membrane filtration processes mathematically a relationship is needed which relates the solute concentration at the membrane surface to that in the bulk and permeate solution, the membrane flux, and the fluid flow conditions in the boundary layer between membrane surface and bulk solution. There are two basic approaches to this problem [159]:

- Application of the so-called film model with the appropriate mass transfer coefficients to describe solute transport into and out of the boundary layer.
- Solution of the transport equations for the fluid velocity field to obtain an expression for the local concentration at any point in the feed solution.

Concentration polarization without precipitation of solutes at the membrane surface can be described reasonably well as a function of the various hydrodynamic parameters and membrane and feed solution properties by the film model. The more rigorous treatment of concentration polarization is based on a material and momentum balance. The numerical solution of the transport equations for the fluid and the solutes is rather complex even after introducing certain simplifications such as complete solute rejection, concentration-independent transport coefficients, and no diffusive transport parallel to the

membrane surface. Mathematical modeling is even more difficult when concentration polarization leads to precipitation of the solutes at the membrane surface. Here time-dependent effects such as densification of a formed gel or cake layer often influence flux and separation characteristics of the membrane.

6.1.1. *Concentration Polarization without Solute Precipitation*

The treatment of concentration polarization without solute precipitation by the film model assumes turbulent flow with fully developed velocity and concentration profiles in the boundary layer at the membrane surface. The description of concentration polarization in laminar flow is based on considerations analogous to heat transfer in laminar feed flow conditions and must consider entrance and exit effects in the development of the velocity and concentration profiles in the feed solution.

The film model assumes that, even with *turbulent feed flow*, at a certain distance from the entrance a constant laminar boundary layer is established adjacent to the membrane surface in which longitudinal mass transport is negligibly low, so that mass transport within the film can be regarded as one-dimensional in the direction perpendicular to the membrane surface. During the filtration process, a steady state is reached in which the convective transport of solutes to the membrane surface is counterbalanced by a diffusive flux of the retained material back into the bulk solution. Therefore, a constant concentration profile of the retained material in the laminar boundary layer is obtained. This is illustrated in the schematic diagram of Figure 62.

Figure 62. Schematic diagram illustrating the concentration profiles of a component retained by the membrane and the fluxes in the laminar boundary layer at the feed side surface of a membrane under steady-state conditions as assumed in the film model

The material balance for the solute in the differential element of the film is given by:

$$J_s = J_{s,con} - J_{s,diff} \tag{6.1}$$

where J_s is the solute flux through the membrane, $J_{s,con}$ the solute flux toward the membrane by convection, and $J_{s,diff}$ the solute flux from the membrane surface into the bulk solution by diffusion.

Furthermore:

$$J_s = J_v C_s^p, \; J_{s,diff} = -D_s \frac{d\,C_s}{d\,z}, \text{ and } J_{s,con} = J_v C_s \tag{6.2}$$

where J_v is the membrane volume flux, D_s is the diffusion coefficient, and dC_s/dz is the concentration gradient of the solute in the boundary layer solution.

Combination of Equations (6.1) and (6.2) and integrating with the boundary conditions $C_s = C_s^w$ at $z = 0$ and $C_s = C_s^b$ at $z = Z_b$ leads to:

$$\frac{J_v Z_b}{D_s} = \ln \frac{C_s^w - C_s^p}{C_s^b - C_s^p} \tag{6.3}$$

where Z_b is the boundary layer thickness, C_s^p the permeate solute concentration, and C_s^w and C_s^b are the solute concentrations in the feed solution at the membrane wall and in the bulk.

The membrane rejection R relates the permeate concentration to the concentration at the membrane wall:

$$R = 1 - \frac{C_s^p}{C_s^w} \tag{6.4}$$

Combination of Equations (6.3) and (6.4) leads to:

$$\frac{C_s^w}{C_s^b} = \frac{\exp \frac{J_v Z_b}{D_s}}{R + (1 - R) \exp \frac{J_v Z_b}{D_s}} \tag{6.5}$$

In Equation (6.5) the concentration polarization is expressed as the ratio of the solute concentration at the membrane surface C_s^w and that in the bulk solution C_s^b. It is a function of the membrane flux J_v, the thickness of the boundary layer Z_b, the diffusion coefficient of the solute in the boundary layer solution D_s, and the membrane solute rejection R.

To describe the concentration polarization under various feed flow conditions a solute mass transfer coefficient k_s is introduced. Assuming that the membrane flux is small compared to the feed flow parallel to the membrane surface the mass transfer coefficient can be expressed by:

$$k_s = \frac{D_s}{Z_b} \tag{6.6}$$

where k_s is the solute mass transfer coefficient, D_s is the solute diffusion coefficient in the boundary solution, and Z_b is the boundary layer thickness.

Introducing Equation (6.6) into Equation (6.5) leads to:

$$\frac{C_s^w}{C_s^b} = \frac{\exp \frac{J_v}{k}}{R + (1 - R) \exp \frac{J_v}{k}} \tag{6.7}$$

Equation (6.7) describes the concentration polarization as a function of the filtration rate, the membrane rejection, and the mass transfer coefficient. The filtration rate and the membrane rejection can easily be measured. The mass transfer coefficient is more difficult to determine. However, empirical correlations developed for various feed solution flow regimes under the assumption of steady-state conditions can be used to estimate the mass transfer coefficient as a function of the feed flow velocity and the filtration device geometry. These correlations may be expressed in a very general form by the Sherwood, Reynolds, and the Schmidt numbers [160]:

$$Sh = a\, Re^b Sc^c \left(\frac{d_H}{L}\right)^d \tag{6.8}$$

where *Sh, Re*, and *Sc* are respectively the Sherwood, Reynolds, and Schmidt numbers, d_H is the hydraulic diameter or other characteristic dimension, *L* the length of the feed flow duct, which may be a channel or a tube, and *a, b, c*, and *d* are constants which are characteristic for different filtration system geometries and which must be experimentally determined.

The Sherwood number is given by:

$$Sh = k_s \frac{d_H}{D_s} \tag{6.9}$$

where D_s is the diffusion coefficient.

The Schmidt number is given by:

$$Sc = \frac{v}{D_s} \tag{6.10}$$

where v is the viscosity.

The Reynolds number for turbulent flow in a tube or channel is given by:

$$Re = \frac{d_H u}{v} \tag{6.11}$$

where *u* is the linear velocity.

In a stirred batch cell the Sherwood and the Reynolds numbers can be expressed by the cell diameter D_c, the stirrer speed ω, and the stirrer length *d*. Thus, in a well-stirred batch cell the Sherwood number is given by:

$$Sh = k_s \frac{D_c}{D_s} \tag{6.12}$$

and the Reynolds number by:

$$Re = \frac{\omega\, d^2}{v} \tag{6.13}$$

When the film model is used to describe concentration polarization in turbulent flow regime, it is generally assumed that the flow is fully developed and entrance effects can be neglected. This can be done in most filtration systems that are used in large-scale industrial applications; therefore, exponent *d* in Equation (6.8) is 0. In laminar flow the situation is different, especially in modules consisting of relatively short thin channels. Here, the entrance length often covers the entire channel length.

Combination of Equations (6.5), (6.8), (6.10), (6.12), and (6.13) gives a relation for the mass transfer coefficient in a well-stirred batch cell:

$$\frac{C_s^w}{C_s^b} = \frac{\exp \frac{J_v D_c}{a\left(D_s \omega d^2\right)^{0.66} v^{-0.33}}}{R + (1 - R) \exp \frac{J_v D_c}{a\left(D_s \omega d^2\right)^{0.66} v^{-0.33}}} \tag{6.14}$$

where C_s^w and C_s^b are the solute concentrations at the membrane surface and in the bulk solution, D_s is the solute diffusion coefficient, D_c the diameter of the cell, *d* the stirrer length, v the viscosity of the solution, ω the stirrer speed, J_v the membrane flux, *R* the membrane rejection, and *a* a constant which has a value between 0.1and 0.6 depending on the cell design.

Equation (6.14) shows that concentration polarization for a given feed solution and batch-cell geometry increases with

increasing transmembrane flux and membrane rejection and decreases with increasing stirrer speed.

By introducing the appropriate relation for the hydraulic diameter and the length of the flow duct the concentration polarization can also be calculated for a rectangular channel and a circular tube. The hydraulic diameter is expressed in terms of the channel width *w* and the channel height *h* by:

$$d_{\mathrm{H}} = \frac{2wh}{w+h} \tag{6.15}$$

where *w* is the channel width and *h* the channel height.

Thus, the concentration polarization in a rectangular channel is given by:

$$\frac{C_{\mathrm{s}}^{\mathrm{w}}}{C_{\mathrm{s}}^{\mathrm{b}}} = \frac{\exp \frac{J_{\mathrm{v}}\left(\frac{wh}{w+h}\right)^{0.2} {}_{v}{}^{0.47}}{a\, D_{\mathrm{s}}^{0.66} {}_{u}{}^{0.8}}}{R + (1-R) \exp \frac{J_{v}\left(\frac{wh}{w+h}\right)^{0.2} {}_{v}{}^{0.47}}{a\, D_{\mathrm{s}}^{0.66} {}_{u}{}^{0.8}}} \tag{6.16}$$

where *w* is the channel width, *h* the channel height, and *u* the linear feed flow velocity.

The concentration polarization in a tubular membrane device can be calculated accordingly to:

$$\frac{C_{\mathrm{s}}^{\mathrm{w}}}{C_{\mathrm{s}}^{\mathrm{b}}} = \frac{\exp \frac{J_{\mathrm{v}} r_{\mathrm{t}}^{0.2} {}_{v}{}^{0.47}}{a\, D_{\mathrm{s}}^{0.66} {}_{u}{}^{0.8}}}{R + (1-R) \exp \frac{J_{\mathrm{v}} r_{\mathrm{t}}^{0.2} {}_{v}{}^{0.47}}{a\, D_{\mathrm{s}}^{0.66} {}_{u}{}^{0.8}}} \tag{6.17}$$

where r_{t} is the radius of the tubular membrane device.

The film model which pictures a laminar boundary layer at the membrane surface and a turbulent bulk solution can obviously not be applied to membrane devices with *laminar feed flow*. In laminar flow in thin-channel, tube, or capillary membrane modules the flow velocity is no longer constant over the cross section of the flow channel or capillary, and the velocity and concentration profiles develop over a much longer distance from the channel entrance than in turbulent flow. Therefore, entrance effects cannot be neglected in most commercially available membrane modules operated with laminar feed flow when the concentration polarization effects are described mathematically. Concentration polarization in laminar flow can be estimated with reasonable accuracy by describing the mass transfer in analogy to heat transfer in laminar flow by the Reynolds, the Schmidt, and the Sherwood numbers, taking the entrance length into account. The Sherwood number for laminar flow devices can be expressed by [161]:

$$Sh = a\left(ScRe\frac{d_{\mathrm{H}}}{L}\right)^{0.33} \tag{6.18}$$

In filtration processes with laminar flow the concentration polarization can be calculated as a function of the flow velocity, the channel height, and the channel length by combination of Equations (6.5), (6.6), and (6.18).

Although the film model assumes several simplifications such as steady-state conditions, that is, no variations in the concentration profile with time, no mass transport parallel to the membrane surface due to concentration or density gradients, and fully developed velocity profile in the turbulent flow regime, it has proved to be quite useful for describing concentration polarization in reverse osmosis and ultrafiltration under various feed flow conditions as long as no solutes precipitate at the membrane surface. The same is true for the treatment of concentration polarization in membrane modules with laminar flow.

The characteristic constants for the calculation the concentration polarization in practically used membrane filtration modules with turbulent and laminar flow are summarized in Table 6.

Table 6. Mass transfer correlation for the constants *a, b, c*, and *d* under various hydrodynamic feed flow conditions

Flow regime	Module geometry	Hydraulic diameter d_{H}	Characteristic constants			
			a	***b***	***c***	***d***
Turbulent	channel	$\frac{2hw}{h+w}$	0.023	0.8	0.33	0
Laminar	channel	$\frac{2hw}{h+w}$	1.62	0.33	0.33	0.33
Turbulent	tube	r_{t}	0.023	0.8	0.25	0
Laminar	tube	r_{t}	1.86	0.33	0.33	0.33

r_{t} = tube radius, *h* = channel height, *w* = channel width.

The *rigorous analysis* of concentration polarization involves the solution of the general transport equations for fluid and solute (i.e., the mass balance of solute and solvent and the momentum balance). The solution of the coupled continuity and

momentum equations is mathematically rather complex and it becomes even more complicated in the case of significant viscosity changes or precipitation of solutes at the membrane surface due to concentration polarization [159].

6.1.2. *Concentration Polarization with Solute Precipitation at the Membrane Surface*

In ultrafiltration and even more so in microfiltration the simple film model is no longer applicable because the feed solutions contain macromolecular components or suspended materials and the membrane fluxes are generally significantly higher than in reverse osmosis [162], [163]. Due to the relatively low diffusion coefficient of macromolecules or suspended particles, diffusive mass transport of components retained by the membrane from the membrane surface back into the bulk solution is slow and can not counterbalance the convective mass transport towards the membrane. Thus, the solute concentration at the membrane surface often exceeds the solubility of the feed solution constituents. This results in the precipitation of the feed solution components at the membrane surface and the formation of a dense solid layer on the membrane surface, which adds an additional hydrodynamic resistance to the membrane flux. When the membrane surface concentration reaches the solubility limit of the feed water constituents, the concentration difference between the membrane surface and the bulk solution and thus the diffusive transport from the membrane surface into the bulk solution reaches its maximum value. If the membrane flux and thus the convective solute transport towards the membrane is increased by increasing the hydrostatic pressure, more solutes are transported towards the membrane than can diffuse back. The additional solutes also precipitate and increase the thickness of the layer at the membrane surface and thus increase its resistance correspondingly, and in spite of an increase in the hydrostatic pressure driving force the membrane flux is not further increased. That means that in ultrafiltration and microfiltration of solutions containing high molecular components with limited solubility the membrane flux becomes independent of the hydrostatic pressure driving force as soon as these components precipitate and form a solid layer at the membrane surface. Typical results obtained in ultrafiltration of macromolecular solutions that precipitate at the membrane surface when a certain hydrostatic pressure or feed solution concentration is exceeded is shown in Figure 63. Here, membrane fluxes obtained when filtering hemoglobin solutions of different concentrations through an ultrafiltration membrane are shown as a function of the applied hydrostatic pressure and the hemoglobin concentration. The filtration apparatus is a stirred batch cell operated at constant stirrer speed. With pure water the membrane flux is directly proportional to the applied hydrostatic pressure. With the hemoglobin solution the membrane flux depends on the applied pressure only at very low pressures and approaches a constant, pressure-independent value at higher pressures. This value is a function of the hemoglobin concentration and is lowest at the highest concentration. Similar membrane flux – pressure relations are obtained in all filtration tests with feed solutions that contain macromolecular or particulate components which have low diffusivities and thus tend to precipitate at the membrane surface. Under conditions of precipitation-layer formation at the membrane surface the membrane flux can only be increased by a decrease in the boundary layer thickness or the bulk solution concentration. The boundary layer in membrane separation processes depends on hydrodynamic conditions of the system and depends on the degree of mixing, that is, on the Reynolds number achieved in the feed solution in turbulent flow or the channel height or capillary diameter under laminar flow conditions. The flux decline due to the formation of a precipitate layer also depends on the feed water constituents. Some components, such as proteins, dextrans, and metal oxides, form rather dense layers that affect the membrane flux significantly, while other materials, such as rigid particles, have a lesser effect on the flux.

Figure 63. Ultrafiltration fluxes of water and hemoglobin solutions of different concentrations determined as a function of the hydrostatic pressure in a stirred batch cell at constant stirrer speed of 1800 rpm

The effect of the boundary layer thickness on the membrane flux has been demonstrated in several studies [164], [165]. Figure 64 shows the ultrafiltration flux of 1 % bovine albumin (M = 69 000) and 1 % dextran 110 (M = 110 000) as a function of the stirrer speed determined in a batch cell at 5 bar hydrostatic pressure [166]. With increasing stirrer speed, that is, decreasing boundary layer thickness, the membrane flux increases.

Figure 64. Membrane flux determined in a stirred batch cell with 1 % solutions of dextran 110 and bovine albumin at different stirrer speeds and constant hydrostatic pressure of 5 bar

The experimental results show that in the case of precipitation of solute at the membrane surface, as in ultrafiltration and more so in cross-flow microfiltration, the hydrodynamic resistance to membrane flux is not only a function of the membrane properties but is also strongly affected by the gel or cake layer formed by the retained solutes at the membrane surface. A simpler approach to describe the membrane flux in case of formation of a gel or a cake layer is to assume that the osmotic pressure of the feed solution in micro- and ultrafiltration can be neglected and express the flux in terms of the resistances of the membrane and the layer in series [167], [168]:

$$J_v = A\frac{1}{R_m + r_1\Delta z_1}\Delta p \qquad (6.20)$$

where J_v is the membrane flux, R_m the hydrodynamic resistance of the membrane, r_l the specific resistance of the layer, Δz_1 the thickness of the layer, Δp the hydrostatic pressure driving force, and A the membrane area.

Formation of a gel or cake layer in micro- and ultrafiltration is illustrated in Figure 65. This figure shows schematically a membrane, the gel layer at its surface, and the concentration and hydrostatic pressure profiles in the bulk solution, the laminar boundary layer, the gel layer, and the membrane. When the concentration of the retained solute at the membrane surface C_s^w reaches the gel layer concentration C_s^g, maximum diffusive transport of retained components from the membrane surface back into the bulk solution is attained. In the description of concentration polarization in terms of the film model it is assumed that diffusion is the only mechanism in the laminar boundary layer for the transport of components from the membrane surface to the bulk solution, and that in the steady state diffusive transport is just counterbalanced by the convective transport towards the membrane. This means that an increase in the hydrostatic pressure will lead only to short-term increase of the membrane flux and convective transport of solutes towards the membrane surface. Since diffusive transport from the membrane into the bulk solution is independent of the applied hydrostatic pressure, and additional components transported towards the membrane surface will precipitate and lead to an increase in gel layer thickness, the overall cake layer resistance will increase until the membrane flux has dropped back to its original value. This means that the membrane flux in ultra- or microfiltration is independent of the applied hydrostatic pressure when a gel layer is formed due to precipitation of the retained components at the membrane surface and it depends only on the transport of these components back into the bulk solution.

Figure 65. Schematic illustrating concentration polarization with the solutes forming a gel or cake layer at the membrane surface (C_s^b and C_s^w are the solute concentrations in the bulk solution and at the membrane wall, Δp is the pressure difference between the permeate and the feed, and J_v the filtrate rate)

Under conditions of precipitation of retained components at the membrane surface the membrane flux can only be increased by increasing the backtransport of the retained components into the bulk solution. This can be done, for example, by decreasing the boundary layer thickness or decreasing the bulk solution concentration, as can be seen from Equations (6.21) and (6.22), which describe the mass transport in the laminar boundary layer in a filtration device with turbulent bulk flow. For simplicity it is assumed that the dissolved components are completely retained by the membrane (i.e., $R = 1$):

$$\frac{C_s^w}{C_s^b} = \exp \frac{J_v Z_b}{D_s} \tag{6.21}$$

where C_s^b and C_s^w are the solute concentrations in the bulk solution and at the membrane surface, which is identical to the gel layer concentration C_s^g and constant for a given temperature and pressure. With $C_s^w = C_s^g$ = const. the flux is determined according to Equation (6.21) only by the bulk solution concentration and the boundary layer thickness. For certain mass transfer conditions and bulk solution concentration it is given by:

$$J_v = \frac{D_s}{Z_b} \ln C_s^b = k_s \ln C_s^b \tag{6.22}$$

Figure 66 shows the membrane flux obtained for three different feed solution concentrations in the filtration of solutions with constituents that precipitate at the membrane surface as a function of the applied hydrostatic pressures, as calculated by Equation (6.22). The flux versus pressure curves in Figure 66 show the same general pressure – flux relation as the experimental data obtained in ultrafiltration experiments with hemoglobin solutions of different concentrations (Fig. 63). The flux of pure water increases linearly with the applied pressure. The flux of a solution also increases linearly with pressure until a certain flux is attained. A further increase in pressure does not lead to a permanent increase in flux since the concentration of the retained solutes at the membrane surface has reached the solubility limit and precipitation occurs. The precipitated solute forms a dense layer which grows in thickness and in hydrodynamic resistance when, due to an increase in the applied pressure, the flux through the membrane is increased for a short time period and then reaches its former value again. The gel or cake layer at the surface of a micro- or ultrafiltration membrane not only impairs the membrane flux, but it can also influence separation properties of the membrane by acting as a permeable membrane which retains lower molecular weight materials not rejected by the membrane [158]. Especially in fractionation of biological fluid mixtures such as blood the formation of a gel layer impairs the entire process and can make a separation of different molecular weight components impossible.

Figure 66. Schematic showing the permeate flux as a function of the applied pressure for the filtration of gel-layer-forming feed solutions of different concentrations

With the formation of a gel or cake layer during filtration of macromolecular or particulate solutions or suspensions with high-flux membranes, mathematical modeling of the process becomes significantly more complex, because the specific resistance of the gel layer depends on the layer-forming components and can be very different for different components. While some rigid materials such as latex balls form layers that resemble the packing of spheres, other materials such as certain proteins form gel-type layers. Many gel layers change their structure with time and their resistance often increases with time.

Furthermore, because of the low diffusivities of macromolecules and particles, diffusion can no longer be the only means of transportation of the components retained by the membrane in micro- and ultrafiltration. Grossly simplified, the process can be described as a three-step procedure (Fig. 67). In the gel layer the material retained by the membrane is more or less solidly integrated in a structure. The strength of this structure will depend on the intrinsic properties of the material but also on the hydrostatic pressure and eventually on the “age” of the gel layer. The first step in the process of bringing the material

back into the bulk solution therefore is to release it from the structure into the solution at the boundary layer. If the material is in solution it can diffuse or be transported by other means such as convection into the bulk solution. Steps 2 and 3 of the transport process are in parallel, while steps 1 and 2 or 3 are in series.

Figure 67. Schematic illustrating the mechanism of the transport of components retained by the membrane and accumulated in a gel layer from the membrane surface back into the bulk solution

In parallel processes, the fastest is the overall rate-determining step, and in consecutive processes the slowest is rate-determining. In ultra- and microfiltration with gel layer formation it is quite likely that the first step, that is, the release of the material from the gel layer structure, is the rate-determining step, and of the two parallel steps convective transport is fastest.

In many ultrafiltration tests a flux decline with time is observed even when all other operating parameters are kept constant. The original membrane flux can usually be restored when the membrane has been cleaned thoroughly with a proper solution. This is demonstrated in Figure 68, which shows schematically the results of a typical filtration test.

Figure 68. Membrane flux obtained during ultrafiltration of cheese whey at constant operating conditions but with daily cleaning periods as function of time (schematic)

The flux decline with time when all operating parameters are kept constant, as shown in Figure 68 and observed in many practical ultrafiltration tests, is difficult to explain with flow condition arguments only. It can, however, be rationalized by the assumption that the rate-limiting step for the transport of the material retained at the membrane surface into the bulk solution is the release rate of the material from the gel structure. This rate may well decrease with time when the gel structure ages and becomes more compact under pressure [169].

Modeling the mass transport at the membrane surface in micro- and ultrafiltration mathematically in terms of the hydrodynamic feed flow conditions, with inclusion of all phenomena observed in practical separation problems, is rather difficult when a gel layer has formed and the mass transfer at the membrane surface is no longer just a function of the diffusion coefficient and boundary layer thickness. Many mathematical models use fitting parameters and can be applied only to very specific conditions of membranes, feed solutions, and process parameters. A general model that fits all feed solutions and process parameters seems to be too complex to be of practical value.

6.2. Membrane Fouling and its Causes

In the literature the term “membrane fouling” is often used to describe a long-term flux decline caused by accumulation of certain materials at the membrane surface. The consequences of membrane fouling are obvious, but its causes are often not very clear [169], [170], [172]. Formation of a gel or cake layer is one cause of membrane fouling. Gel or cake layers can be formed by a variety of materials including inorganic precipitates such as $CaSO_4$, $Fe(OH)_2$, and other metal hydroxides; organic materials such as proteins, humic acids, and other macromolecular materials; and biological components such as microorganisms and their metabolic products. Membrane fouling can also occur without concentration polarization (i.e., direct transport to the membrane surface as in any mass separation process). The attachment of the substances to the membrane surface may be caused by adsorption due to hydrophobic interactions, van der Waals forces, or electrostatic forces. The fouling layer itself can be porous and thus permeable to aqueous solutions, as in the case of some inorganic precipitates, or highly impermeable when the layer consists of films of mineral oils or hydrophobic surfactants. The fouling mechanism also depends on the membrane process. In electrodialysis fouling is caused mainly by precipitation of polyelectrolytes or sparingly soluble salts such as $CaSO_4$ or $CaCO_3$. Membrane fouling in electrodialysis affects mainly anion-exchange membranes because most of the colloidal and macromolecular polyelectrolytes present in natural waters (e.g., humic acids and proteins) are negatively charged. In ultra- and microfiltration of biological solutions, but also in reverse-osmosis seawater desalination, biological fouling is a severe problem affecting the economics of the processes. In biomedical applications protein adsorption and protein denaturation at the membrane surface often impair the performance of the membranes.

The difference between concentration polarization and membrane fouling or scaling is illustrated schematically in Figure 69. Concentration polarization is a reversible process based on diffusion and takes place over a few seconds; it can be described adequately by a simple mathematical model and easily controlled by proper process design. Fouling is generally irreversible and the flux decline takes place over many minutes, hours, or even days. A constant flux is generally not reached. Membrane fouling is more difficult to describe and to control by experimental means. Membrane fouling is determined by a variety of different parameters including the feed solution constituents and their concentration, membrane material, and the fluid-dynamic system design. Membrane fouling can be caused by simple precipitation of insoluble materials or by reversible or irreversible adsorption of components at the membrane surface and within the membrane pores.

Figure 69. Schematic illustrating the difference between the flux decline due to concentration polarization and due to membrane fouling

The means of preventing or at least controlling membrane fouling are as heterogeneous as the different materials and mechanisms causing the fouling [171], [172]. The main procedures to avoid or control fouling involve:

- Pretreatment of the feed solution
- Membrane surface modifications
- Hydrodynamic optimization of the membrane module
- Membrane cleaning with appropriate chemical agents

Pretreatment of the feed solution can include chemical precipitation, prefiltration, pH adjustment, chlorination, and carbon adsorption. In some membrane module designs, for instance, hollow-fiber modules, the elimination of all particulate materials is of great importance for the proper function of the membrane.

Membrane surface modifications include the introduction of hydrophilic moieties or charged groups in the membrane surface by chemical means or plasma deposition.

Increasing the shear rate imposed by the feed solution on the membrane surface will in many cases reduce membrane fouling. High feed flow velocities and proper module design are efficient tools in controlling membrane fouling.

When, in spite of an adequate membrane and module design, the membrane flux decreases with operating time to an unacceptably low value it is necessary to clean the membrane to restore the flux in part or completely. Typical cleaning agents are acids and bases such as HNO_3 and NaOH, complexing agents, enzymes, and detergents. Another very effective method to minimize the effects of membrane fouling in microfiltration is backflushing, in which the applied pressure is reversed and the permeate pushed through the membrane to lift off fouling material precipitated on the feed side membrane surface and wash it out of the filtration device. Backflushing is done at certain time intervals for a few seconds.

6.3. Concentration Polarization in Other Membrane Separation Processes

In other membrane separation processes of technical relevance concentration polarization is of lesser significance than in reverse osmosis or ultrafiltration. It can generally be controlled and its detrimental effects be minimized by proper process design.

6.3.1. *Concentration Polarization in Dialysis*

In dialysis, concentration polarization is an accepted phenomenon. There is always depletion of the components in the boundary layer at the membrane surface facing the feed solution and accumulation at the membrane surface facing the dialysate (Fig. 70). However, the differences between the concentrations at the membrane surfaces and in the bulk solutions is low, because dialysis membranes are rather thick compared to the laminar boundary layers at their surfaces, and the transport in the membrane is rate-limiting for the overall mass transfer from the feed to the dialysate bulk solution. Thus, in dialysis concentration polarization effects are small.

Figure 70. Schematic illustrating the effects of concentration polarization in dialysis

6.3.2. *Concentration Polarization in Electrodialysis*

In electrodialysis, concentration polarization decreases the ion concentration at the membrane surface facing the diluate cell and increases the concentration at the membrane surface facing the concentrate cell of the electrodialysis stack. The concentration increase may lead to a precipitation of salts. The concentration decrease lowers the limiting current density. Since the required membrane area is inversely proportional to the limiting current density, concentration polarization in electrodialysis has direct consequences for the overall process economics. It is controlled by using cell design and the flow velocities in the system to minimize the thickness of the laminar boundary layers at the membrane surfaces.

6.3.3. *Concentration Polarization in Pervaporation*

In pervaporation, concentration polarization can occur on both sides of the membrane. As in dialysis the boundary layer at the membrane surface facing the feed solution is depleted of the preferentially permeating components, which are then enriched at the membrane surface facing the permeate [173]. In pervaporation, concentration polarization is generally controlled by decreasing the laminar boundary layer thickness through hydrodynamic measures. This can lead to problems when high-flux thin-film composite membranes are used. At the permeate side the laminar boundary layer is always as thick as the porous substructure, and severe concentration polarization and capillary condensation may occur on the permeate side of the membrane. If the solubility of the permeating component in the feed solution is low the boundary layer at the feed side of the membrane may be depleted of the permeating component and the membrane flux and separation efficiency may be severely impaired. This, for example, is the case when organic solvent – water mixtures of limited solubility are treated.

6.3.4. *Concentration Polarization in Gas Separation*

In the separation of gases by solution-diffusion membranes, concentration polarization is of lesser importance and has generally little effect on the overall efficiency of the process. The reason is that the diffusivity of gases in the gas phase is much higher than in a solid polymer phase. Therefore, the transport rates in the boundary layer are comparatively high and there is less accumulation or depletion of components at the membrane surface. Nevertheless, concentration polarization in gas separation can not in all cases be neglected and must also be controlled by proper system design and flow conditions of the gases on the feed and permeate side of the membrane.

1. Introduction

Mercaptoacetic acid [*68-11-1*], thioglycolic acid, $HSCH_2COOH$, is the simplest and industrially most important mercaptocarboxylic acid. The compound was first prepared in 1862 by CARIUS from chloroacetic acid and potassium hydrogen sulfide. There are numerous patents dealing with the applications of mercaptoacetic acid in the cosmetic and plastic industries.

2. Physical Properties

Mercaptoacetic acid is a clear, colorless liquid with a characteristic odor. Some physical properties are as follows:

M_r	92.11
mp	−16.5 °C
bp (2.3 kPa)	110–112 °C
bp (0.1 kPa)	79–80 °C
n_D^{20}	1.5027
d_4^{20}	1.325
Heat of combustion	1450 kJ/mol
Vapor pressure (30 °C)	0.02 kPa
Vapor density	3.18
Flash point	126 °C
Dissociation constants (in $NaClO_4$ solution at 20 °C)	
K_1	$(3.82 \pm 0.1)\,pK_a$
K_2	$(9.30 \pm 0.1)\,pK_a$

Mercaptoacetic acid is miscible with water, mono- and polyalcohols, ethers, ketones, esters, chlorinated hydrocarbons, and aromatic hydrocarbons, but not with aliphatic hydrocarbons. The esters of mercaptoacetic acid are mostly colorless liquids with characteristic odors. The cetyl and stearyl esters are pale yellow waxes [1].

3. Chemical Properties

Mercaptoacetic acid has two reactive centers: the mercapto group and the carboxyl group. The compound forms salts of the carboxyl and mercapto groups, esters, amides, anilides, thioethers, etc. Oxidation of mercaptoacetic acid, which occurs even on standing in air, gives dithiodiglycolic acid [*505-73-7*], $HOOCCH_2SSCH_2COOH$. The reaction is accelerated by traces of metals such as copper, iron, and manganese [2]. In concentrated solutions (80 %), linear and cyclic polycondensation products are formed, including a tetracarboxylic acid with a 1,4-dithiane ring structure [3]. Thioethers are formed by reactions of the sodium or potassium salts of the mercapto group with alkyl halides or by addition of mercaptoacetic acid or its derivatives to double or triple bonds. Depending on the catalyst used, either the Markovnikov or anti-Markovnikov product is obtained [4]. Mercaptoacetic acid and its derivatives react with aldehydes and ketones to form mercaptals, mercaptols, or α,β-unsaturated thioethers. The addition reactions are catalyzed by acids (e.g., mineral acids and toluenesulfonic acids) [5]. In the formation of oxathiolanes, the mercapto and carboxyl groups react simultaneously with a carbonyl group. For example, the reaction of mercaptoacetic acid with cyclohexanone affords 2,2-pentamethylene-1,3-oxathiolane-5-one [6]. The strongly reducing nature of mercaptoacetic acid is of importance both in investigations of biochemical redox and enzyme systems and in industrial applications such as cold-waving preparations and modification of wool. The use of mercaptoacetic acid for the permanent waving

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a16_265

of hair is based on the reductive cleavage of the cystine disulfide bridges of keratin [7].

4. Production

Industrially, mercaptoacetic acid is produced from chloroacetic acid or its salts and sodium or potassium hydrogen sulfide. Thiodiglycolic acid, dithiodiglycolic acid, and glycolic acid may be formed as side products. The mercaptoacetic acid is isolated from the acidified reaction mixture by extraction with organic solvents (ethers, alcohols, or chlorinated hydrocarbons) and purified by distillation. Both batch and continuous processes have been described in the patent literature as well as processes that operate under a partial pressure of hydrogen sulfide or carbon dioxide [8]. In one process, sulfur wastes, which arise from the reduction of aromatic nitro compounds, are used instead of alkali-metal hydrogen sulfides [9], while in another process mercaptoacetic acid is obtained by cleavage of imidazolyl mercaptoacetic acid with sodium sulfide [10]. It can also be produced through cleavage of the Bunte salt NaO_3SSCH_2COOH, prepared from chloroacetic acid and sodium thiosulfate, with dilute sulfuric acid; by reduction of dithioglycolic acid (prepared from chloroacetic acid and alkali-metal polysulfides); and by decomposition of the xanthate ester obtained from chloroacetic acid and potassium ethylxanthate [11]. Anhydrous mercaptoacetic acid is obtained by distillation of technical mercaptoacetic acid with toluene. During production, it is important to avoid contact of the mercaptoacetic acid with metals that catalyze its dimerization.

Esters of mercaptoacetic acid can be produced either by esterification with alcohols, whereby the alcohol can simply be used as the extractant after the synthesis of the acid, or by reaction of the corresponding alkyl chloroacetate with sodium thiosulfate [12].

5. Analysis

Mercaptoacetic acetic acid gives color reactions with numerous metal salts. Iron salts and sodium pentacyanonitrosylferrate(III) give a violet coloration [13]. Mercaptoacetic acid is analyzed quantitatively by titration with iodine [14]. Spectroscopic and chromatographic methods in industrial use include determination by HPTLC [15], analysis of cold-waving preparations by HPLC [16], and detection by gas chromatography [17]. Reference spectra for spectroscopic investigations can be found in [18], [19].

6. Transportation and Storage

Commercial forms of mercaptoacetic acid are the 99 % acid (d_4^{20} 1.325) and the 80 % acid (d_4^{20} 1.27). Standardized mercaptoacetic acid should contain not more than 2 % dithiodiglycolic acid and a maximum of 1 ppm iron, lead, copper, and arsenic [20]. Isooctyl mercaptoacetate [*25103-09-7*] and glycerol monothioglycolate [*30618-84-9*] are sold water-free. Mercaptoacetic acid must be transported in stainless steel (V_4A, V_2A) or polyethylene-lined polyester containers. The following transportation codes apply [21]:

IMDG (GGVSee)	Class 8 D E – F 8154 UN no. 1940
RID (GGVE)	Class 8 Rn 801 Section 32 b
ADR (GGVS)	Class 8 Rn 2801 Section 32 b
ADNR	Class 8 Rn 6801 Section 32 b
GefStoffV	607-090-00-6
GB Blue Book	Corrosives and IMDG code E 8154
United States	CFR 49: § 172.101 Corrosive M
ICAO/IATA-DGR	Class 8 UN no. 1940

7. Toxicology

Contact with mercaptoacetic acid leads to irritation of the skin and eye. The vapor causes irritation of the mucous membranes, coughing and shortness of breath after inhalation, badly healing wounds, and blisters [22]. Protective gloves and eyewear are therefore necessary when working with mercaptoacetic acid [22]. The TLV value has been set at 1 ppm (5 mg/m^3) [23]. The oral LD_{50} in the rat is 261 mg/kg [24]; more recent tests on mice are reported in [25]. Most derivatives of mercaptoacetic acid and commercial products containing them, for which legal maximum concentrations apply (see → Hair Preparations, Chap. 10.), are considerably less toxic and therefore do not present a health risk in normal use [26].

8. Uses

Since ca. 1950 mercaptoacetic acid and its derivatives, in particular the ammonium and ethanolammonium salts and to an increasing extent glycerol monothioglycolate, have been used for the production of cold-waving preparations [27] (→ Hair Preparations, Chap. 6.). The calcium salt is used in depilatories. Mercaptoacetic acid and derivatives are also used for industrial unhairing (e.g., leather production) and for permanent forming of wool (e.g., in hat making). Sulfur-containing organotin compounds of the type dialkyltin bis(isooctyl thioglycolate) and alkyltin tris(isooctyl thioglycolate) are the most important thermo-stabilizers for PVC [28]. The low toxicity and extremely low migration of, for example, dioctyltin bis(isooctyl thioglycolate) with various amounts of octyltin tris(isooctyl thioglycolate), has led to their use worldwide for the production of food packaging materials and pipes for drinking water [29]. Esters, particularly of higher alcohols such as isooctanol and decanol, and amides of mercaptoacetic acid are used as polymerization catalysts and antioxidants for the production of plastics and rubbers [30]. The sodium salt of mercaptoacetic acid is a component of the Brewer nutritive medium for anaerobic bacteria [31].

Mercaptoacetic acid is used in analytical chemistry for the separation of iron and aluminum and as a reagent for iron [13], nitrite, uranium, vanadium, chromium, copper, molybdenum, and palladium [32]. It is used in fast atom bombardment mass spectrometry as a matrix compound [33]. A mild process for the isolation of lignin involves the use of mercaptoacetic acid with boron trifluoride [34]. Other economically important uses include the production of derivatives of thiophene and dihydrothiophene, which are used as precursors for pharmaceuticals [35], and the synthesis of intermediates for dyes (e.g., *S*-aryl mercaptoacetic acids). A review of chelate complexes of mercaptoacetic acid is given in [36]. World production of mercaptoacetic is estimated to be $15-20\times10^3$ t/a.

1. Introduction

Matthias Simon

Mercury [7439-97-6] (also called quicksilver), symbol Hg from the Greek *hydor* = water and *argyros* = silver, atomic number 80, A_r 200.59, was known as early as 1000 B.C. because of its liquid state at room temperature (melting point – 38.89 °C).

The discovery in 1938 of 1 kg of the metal in 2500-year-old sand layers on the eastern coast of Greece indicates that mercury was used in the extraction of gold at an early date [1]. Mercury was mentioned about 200 B.C. in India as well as in China (Han dynasty).

As early as 1556, GEORGES BAUER, known as AGRICOLA, reported five different methods for extracting mercury from its ores [2]. He also realized that mercury vapors are heavier than air and that they could therefore conveniently be trapped in condensers beneath the reaction vessel.

Because of the considerable vapor pressure of mercury even at room temperature and the toxicity of its vapors (see Chap. Toxicology and Occupational Health), particularly safe and reliable methods must be used in the extraction of mercury to avoid releasing even the slightest trace of the metal into the environment. The problem of gas and water purification is therefore particularly important (see Chap. Environmental Protection).

[Top of Page]

2. Properties

Matthias Simon and Peter Jönk

2.1. Physical Properties

Mercury is a silvery-white, shiny metal, which is liquid at room temperature. The most important physical properties are listed below:

Isotope masses (ordered according to decreasing abundance)	202, 200, 199, 201, 198, 204, 196
mp	– 38.89 °C
bp (101.3 kPa)	357.3 °C
Density (0 °C)	13.5956 g/cm^3
Specific heat capacity	

c_p (0 °C)	0.1397 J g^{-1} K^{-1}
Heat of fusion	11.807 J/g
Heat of evaporation (357.3 °C)	59.453 kJ/mol
Thermal conductivity (17 °C)	0.082 W cm^{-1} K^{-1}
Thermal expansion coefficient β (0 – 100 °C)	1.826×10^{-4} K^{-1}
Electrical conductivity (0 °C)	1.063×10^{-4} m Ω^{-1} mm^{-2}
Crystal structure	rhombohedral
Viscosity (0 °C)	1.685 mPa · s
Surface tension	480.3×10^{-5} N/cm
t_{crit}	1450 °C
p_{crit}	105.5 MPa
Critical density	5 g/cm^3
Evaporation number (25 °C)	0.085 mg K^{-1} cm^{-2}

Mercury has a relatively high vapor pressure, even at room temperature. Saturation vapor pressures at 0 – 100 °C are listed in Table 1 (corresponding to a specified mercury content in air). The temperature dependence of the density of mercury is given in Table 2.

Table 1. Saturation vapor pressure of mercury at different temperatures

t, °C	*p*, Pa	Hg content in air, g/m^3
0	0.026	0.00238
10	0.070	0.00604
20	0.170	0.01406
30	0.391	0.03144
100	36.841	2.40400

Table 2. Density of mercury as a function of temperature

t, °C	Density, g/cm^3	*t*, °C	Density, g/cm^3
– 38.89	13.6902	200	13.1139
0	13.5956	250	12.9957
50	13.4733	300	12.8778
100	13.3524	350	12.7640
150	13.2327		

Mercury vapor is excited to a state of luminescence by electrical discharge (mercury vapor lamps). Ultraviolet radiation is released primarily, it can be used to start and to promote chemical reactions.

The surface tension of mercury is ca. six times greater than that of water, which is the reason for its poor wettability by water.

The dynamic viscosity η of mercury (see Table 3) is of the same order of magnitude as that of water [3].

Table 3. Temperature dependence of the dynamic viscosity of mercury

t, °C	η, mPa · s	*t*, °C	η, mPa · s
– 20	1.855	60	1.367
– 10	1.764	80	1.298
0	1.685	100	1.240
10	1.615	200	1.052

20	1.554	300	0.950
30	1.499	340	0.921
40	1.450		

Some other metals, such as gold, silver, and zinc, dissolve readily in mercury to form amalgams. The solubility of mercury in water is strongly temperature dependent [4]. At room temperature, the solubility is ca. 60 µg/L; at 50 °C, ca. 250 µg/L; and at 90 °C, ca. 1100 µg/L. At low temperature, the addition of sodium chloride reduces the water solubility.

2.2. Chemical Properties

Mercury exists in the oxidation states 0, + 1, and + 2; monovalent mercury is found only in Hg–Hg bonds. The redox potentials at 298.15 K and 101.325 kPa relative to the standard hydrogen electrode are as follows [3]:

		E^0, V
$Hg^{2+} + 2\,e^-$	$\rightleftharpoons$ Hg	+ 0.851
$2\,Hg^{2+} + 2\,e^-$	$\rightleftharpoons$ Hg_2^{2+}	+ 0.920
$Hg_2^{2+} + 2\,e^-$	$\rightleftharpoons$ 2 Hg	+ 0.797
$Hg_2(CH_3COO)_2 + 2\,e^-$	$\rightleftharpoons$ $2\,Hg + 2\,(CH_3COO)^-$	+ 0.511

The standard potentials show that mercury is a relatively noble metal. Metallic mercury dissolves in nitric acid, aqua regia, warm concentrated hydrochloric acid and sulfuric acid. It is sparingly soluble in dilute HCl, HBr, and HI as well as in cold sulfuric acid. Most of its chemical compounds have densities of 5 – 9 g/cm^3. The oxide of mercury (HgO) decomposes at 400 – 500 °C. This effect is utilized in the extraction of mercury from oxidic sources. Mercury forms monovalent and divalent compounds with the halogens fluorine, chlorine, bromine, and iodine. It also forms monovalent and divalent compounds with sulfur.

[Top of Page]

3. Resources and Raw Materials

Matthias Simon

3.1. Deposits

All known mercury ores are relatively lowgrade ores, the average mercury content being ca. 1 %. Because mercury ores lie close to the earth's surface, the mining depth is ca. 800 m at most. The overwhelming proportion of mercury has always been produced in Europe; some of the most important deposits are listed below.Since the 1980s the former Soviet Union, Spain, China, Algeria, Turkey, and the United States have accounted for ca. 90 % of world mining production.

Spain. The deposits at Almadén have been mined for more than 2000 years. Almadén is situated in the southwest of the province of Ciudad Real in New Castile, about 200 km from Madrid, on the northern edge of the Sierra Morena. The ore-bearing deposits are porous sedimentary rocks (sandstone, bituminous shale, Silurian quartzite) that contain mercury sulfide (cinnabar). Needles of coarsely crystalline cinnabar as well as metallic mercury in lenticular ore-bearing bodies are also found over a roughly 20-km stretch in the valley of the Valdeazogues river. The ore is extracted in several mines (San Pedro y San Diego, San Francisco, San Nicolas). The richest strata contained 12 – 14 % mercury at a depth of 170 – 200 m. Mining is carried out today at a depth of 500 m; 1 t of ore yields about one flask of mercury (= 34.473 kg of mercury, corresponding to a 3.5 % mercury content in the ore).

This deposit was probably known to the Celts and Phoenicians, and was mined by the Romans from 150 B.C. These mines were subsequently worked by the Moors, then by the orders of knights, by the Spanish royal house, and from 1525 – 1645 by the Fuggers. Since then the mines have been under state management. From 1499 (when production records start) to the present, ca. 300 000 t of mercury has been mined.

In 1988 Almadén produced ca. 1380 t of mercury. The ore-bearing body has an average mercury content of 5 %. Because of the low price of mercury the plant operates for only a few months of the year. The operating company, Minas de Almadén y Arrayanes SA, is state-owned [5], [6].

Spain, which until 1989 was the world's largest producer of mercury, ceased nine production after 1990, although 100 t of mercury was produced in 1991 from stockpiled materials.China, Mexico, adn Russia were the largest producers in 1992.

Italy. A roughly 25-km-wide, 50-km-long belt running from Monte Amiata to the coast in southern Tuscany contains many closed mines as well as some that are still operating. Although these deposits had been mined by the Etruscans, they were not intensively worked by the Romans, to the benefit of the Spanish mines at Almadén. The Siele mine recommenced operation only in 1846, and the Abbadia San Salvatore mine, at present still the largest, in 1898.

Mercury occurs as cinnabar and metacinnabarite in pyrites, marcasite, antimonite, and realgar, mainly in Eocene sediments (shale, sandstone, marl, limestone) under a covering layer of trachyte. The gangue consists largely of clay or dolomite. The ores contain on average 0.2 – 0.8 % mercury. Mercury extraction is organized by the Monte Amiata works, its latent production capacity being up to 2000 t/a. No mercury has been mined since 1983.

Former Yugoslavia. The third largest mercury deposits in Europe are situated in Idrija in Slovenia, about 40 km west of Ljubljana. These deposits have been worked since 1497. The mines were under Austrian ownership from 1580 to 1918, then under Italian ownership, and finally reverted to former Yugoslavia after World War II.

The tectonics of this region are complicated. Shell marl and shale are impregnated with cinnabar and native mercury, and typically contain admixtures of pyrites, gypsum, and bitumen. The ore contains ca. 0.5 % mercury. Idrija has a capacity of about 600 t/a. About 30 t mercury was mined in 1992. Additional deposits in former Yugoslavia are located at Maškara in Croatia, Berg Avala to the south of Beograd in Serbia, Neumarkt in the Karavanken, and Montenegro.

Algeria. Algeria has become the second largest mercury producer in the western hemisphere after Spain, and in 1986 ca. 690 t of mercury was produced. In 1992 ca 425 t were produced.

Germany. In 1936 a modern mercury works was built at Landsberg near Obermoschel in the northern Pfalz (Palatinate), which had to be closed in 1942 because working the very low-grade ore, containing only 0.1 % Hg, was uneconomical.

Austria. Fahl ore containing 1.8 % mercury is mined in small amounts at Schwaz in the Tyrol. Other deposits at Dollach on the Drava are no longer mined.

Finland. Outokumpu obtains about 100 t of mercury per year from the processing of zinc concentrates.

Former Czechoslovakia. Three important deposits exist: at Kotrbachy, mercury is obtained as a byproduct of a fahl ore. Cinnabar is found southwest of Gelnica in a workable ore containing 0.25 % mercury. Finally, mercury has been obtained in the region between Mernik and Vranov since the end of the 17th century. This production ceased in 1937.

Rumania. Rumania has mercury ores at Zlatna and Baboja in Transylvania.

Turkey. In Turkey about 5 t of mercury is obtained annually from mining operations. At present, because of its low price, mercury is extracted from only two mines, which belong to the state-owned Etibank. The deposits are at Izmir-ödemi ş-Haliköy (1×10^6 t of ore containing 0.25 % mercury), Konya-Ladik, and Konya-Sizma (1.15×10^6 t of ore containing 0.23 % mercury). These deposits alone account for ca. 40 % of the Turkish reserves of mercury [7].

Former Soviet Union. The most important deposits are at Nikotovka in the Ukraine. Per year about 400 t of mercury is produced there from an antimonite ore containing 0.4 % mercury. Cinnabar deposits have recently been discovered in the Crimea, although no further details are available. Additional ore deposits are mined in the Northern Caucasus, Urals, Altai Mountains, and in Turkestan and Dagestan.

China. China has important deposits in the provinces of Yunnan, Hunan, and Kweitschan. The mines at Wanschantschang and Patschai are well known. Mined production was ca. 760 t of mercury in 1987 and 950 t in 1992.

Japan. In Japan, mercury is extracted on the island of Hokkaido.

Canada. Mercury ore deposits are situated in the west of Canada in British Columbia at Pinchi Lake and in the vicinity of Vancouver (Kamloops, Bridge River).

United States. The number of mines in the United States has decreased considerably in the last 20 years. Whereas 149 mines were operating in 1965, only 3 mines were still operating by 1981. The principal mining regions are California and Nevada. Placer, Inc., a subsidiary of the Canadian company Placer Development, accounts for ca. 99 % of production. The average mercury content in the ore is 0.3 – 0.5 %. Mining production in 1992 was ca. 64 t and falling.

Mexico. The 200 known mercury ore deposits are distributed over 20 states. The most important mines are in the provinces of Zacatecas, Guerero, Durango, Chihuahua, Guanajuato, San Luis Potosi Aguascalientes, and Queretaro; total mercury production is some 700 t/a.

South America. South America is of only minor importance as a mercury producer. Chile occupies first place among the mercury-producing countries. The Santa Barbara mine at Huancavelica in Peru is now exhausted, although it supplied substantial amounts of mercury in the 17th and 18th centuries : some 50 000 t was used for precious-metal extraction. Small amounts of mercury are mined in Venezuela and Bolivia.

A U.S. estimate made in 1983 gave the following amounts of mercury extracted by mining operations [8]:

Spain	50 000 t
People's Republic of China	17 200 t
Former Soviet Union	17 200 t
Former Yugoslavia	17 200 t
Italy	12 100 t
United States	12 100 t
Other countries	29 000 t
World total	154 800 t

Mining activities and exploitation of deposits are, as with most base metals, greatly dependent on current world market

prices. Too low returns have led in recent years to a number of mines being closed, which has resulted in a concentration of plants (less plants with increased production).

3.2. Secondary Sources

Like primary ores, industrial waste containing mercury also contributes to its production. The majority of plants used in chlor – alkali electrolysis employ liquid mercury cathodes, resulting in residues containing 10 % mercury or more. In addition to this major secondary source, mercury batteries, mercury fluorescent tubes, electrical switches, thermometer breakage, and obsolete rectifiers should be regarded as mercury sources.

Although the overall production of mercury has decreased since the 1970s, sufficient potential uses and thus secondary sources remain for the foreseeable future, thanks to the unique properties of this metal.

[Top of Page]

4. Production

Matthias Simon

4.1. Extraction from Primary Sources

4.1.1. *Dressing*

Preliminary concentration is desirable, especially for working low-grade ores. This is often performed in the mine by classification. Because of the brittleness of cinnabar, pieces of ore break easily at the mercury sulfide veins. Crystalline mercury sulfide in brittle ore can be concentrated by using settling tables.

Another method of concentration is the use of a flotation stage (⟶ Flotation) to increase the mercury content. Separation of the antimony and arsenic fractions is particularly important, and the ores are comminuted to grain sizes of ≤ 0.075 mm (200 mesh) in the case of antimony and ≤ 0.5 mm (25 mesh) in the case of arsenic. After comminution, lead(II) nitrate [$Pb(NO_3)_2$], butyl xanthate, and pine oil are added to the first flotation stage. Flotation is performed at pH 7.1. After purification, mercury is selectively floated, and a concentrate of ca. 50 % antimony is obtained. Potassium dichromate ($K_2Cr_2O_7$) is added as reactant. The end concentrate has a mercury content of ca. 70 % [9]. Another way of concentrating mercury by flotation is to add potassium oleate as collector [10].

Only a coarse preliminary grinding to ca. 50-mm grain size is necessary for high-concentration mercury sulfide ores. During subsequent thermal treatment, the ore particles burst because of the high vapor pressure, resulting in further comminution.

4.1.2. *Processing to Metallic Mercury [11], [12]*

The most important starting material for mercury extraction is mercury sulfide (cinnabar, cinnabarite) (see Section Mercury Chalconides); it is nonpoisonous and can be stored and transported without any problem.

The coarsely ground ore is processed in directly or indirectly heated furnaces, retorts, or muffles. Reaction with oxygen begins at 300 °C, according to

$$HgS + O_2 \rightleftharpoons SO_2 + Hg$$

Quicklime can be added as flux to bind the sulfur in solid form. The overall reaction in the *absence of oxygen* is as follows:

$$4\,HgS + 4\,CaO \rightleftharpoons 3\,CaS + CaSO_4 + 4\,Hg$$

In the *presence of oxygen,* the reaction is

$$HgS + CaO + 3/2\,O_2 \rightleftharpoons Hg + CaSO_4$$

Addition of metallic iron in the form of iron filings enables the following reaction to occur:

$$HgS + Fe \rightleftharpoons FeS + Hg$$

Instead of metallic iron, iron oxides can also be used:

$$7\,HgS + 2\,Fe_2O_3 \rightleftharpoons 4\,FeS + 3\,SO_2 + 7\,Hg$$

For this reason, sulfur-resistant steel should be used as construction material. Processing is normally performed with the addition of air, and the sulfur dioxide formed can be converted in a downstream wet scrubber.

4.1.3. *Furnace Systems*

Mercury sulfide-containing ores are processed pyrometallurgically. Distinction is made between *directly* and *indirectly* heated furnaces. This is important because the formation of *stupp* cannot be avoided in pyrometallurgical processing (the word stupp is an Austrian expression that simply means powder; in the case of mercury, a mercury-containing powder). The greater the formation of dust in the furnace, the greater is the occurrence of stupp. Because of the presence of combustion air in the furnace, directly heated furnaces generally create more dust than indirectly heated ones. Mercury in vapor form condenses to some extent on the small dust particles which act as condensation nuclei.

Another difference between directly and indirectly heated furnaces is that mercury vapor in indirectly heated systems is more

highly concentrated because it is not diluted by combustion gases.

Directly Heated Furnaces. Cylindrical Bustamente furnaces, multiple-hearth furnaces, and rotary kilns are used.

The *Bustamente furnace* is still used in Spain (Almadén) [5]. The cylindrical vessel is heated outside the shaft, only the combustion gases come into contact with the ore. A historical feature is that mercury vapors are condensed in air-cooled terracotta pipes.

The *multiple-hearth furnace* is advantageous for working up rich concentrates, mercury waste of a similar type, or stupp. This kind of furnace has been used for many decades in various mercury mines in North America, and in Almadén most of the ore extracted since 1961 has been processed in multiple-hearth furnaces. The hearths and outer walls of the furnaces are built of shaped fireclay bricks. The furnaces are lined with sheet steel. Cast steels with additions of titanium, chromium, and nickel have proved suitable for internal structural elements (stirrer shaft, raking arm). A modern furnace is up to 10 m high, has a diameter of ca. 5 m, and contains up to 16 hearths that are heated with wood, gas, or oil (mainly the upper and lower hearths). An attempt is made to keep the flow velocities for the reaction gas low (maximally 3 m/s) by skillful feeding of the material (if possible by special sliding surfaces at the throats in the case of small hearth interspacings) and by separately installed gas passageways. The amount of flue dust is thereby lowered (0.2 – 3 % of the feedstock), and the formation of stupp is minimized. Addition of combustion air through the insulated hollow shaft and raking arm and, if necessary, preheating of the fuel oil both reduce fuel consumption. By accurate metering of the inlet air, a lower amount of gas can be passed through the furnace, and the capacity of the subsequent condensation unit can be reduced. Table 4 shows some operational examples of multiple-hearth furnaces.

Table 4. Operational data for multiple-hearth furnaces for mercury extraction

	New Almadén	Pershing	Quicksilver Mines
Furnace diameter, m	4.9	4.9	5.5
Number of hearths	6	8	6
Worked material	ore	ore	ore
Throughput, t/d	38	77	50
Fuel consumption per tonne of material	47 L oil	21 L oil	0.15 m^3 wood

With regard to environmental protection, multiple-hearth furnaces are relatively difficult to make gastight and, in some cases, have had to be shut down.

Rotary kilns have been used since 1913 to extract mercury. Rotary kilns and rotary drum furnaces provide a high mercury yield with a good throughput rate of the ore because the reaction temperature can be controlled accurately; the ore does not have to be specially preheated; and material throughput can be regulated.

The ore is ground to about 65-mm particle size before it is charged. Lime, charcoal, or low-temperature coke may be added as fluxes, and the furnaces are heated directly by oil or gas. The furnaces are operated at 320 – 400 °C at the charging head and 700 – 800 °C at the discharge end. For normal furnace sizes and ores, heat consumption is 1×10^6 to 1.25×10^6 kJ per tonne of throughput. Without the addition of coal as flux, this corresponds to up to 30 L of oil or 250 m^3 (STP) of fuel gas per tonne of ore throughput. A disadvantage of rotary kilns is the dust formed by the intense material movement, which leads to increased stupp formation in subsequent condensation and can cause stoppage in the waste-gas line. Flue dust amounting to 0.75 – 6 % of the ore feedstock by weight is observed. In many cases, dust formation can be reduced by fluxes having a sintering effect. Some operating examples of older rotary kilns are listed in Table 5.

Table 5. Operational data for rotary kilns for mercury extraction

Indirectly Heated Furnaces. The basic advantage of indirect heating is the lower gas velocity in the reactor and the higher mercury concentration of the process gas. The furnaces are heated by gas, coal, or by electricity and consist in some cases of clay muffles, vessels lined with fireclay or ceramics, or iron vessels lined with silicon carbide.

F. Krupp – Grusonwerk AG has arranged several tubular individual muffles in a rotary kiln around a thermally insulated, centrally aligned shaft. A rotary kiln constructed from two concentric tubes was developed several years later. The ore passes continuously through the inner tube; the outer tube is heated. A highly thermally conducting, gastight silicon carbide is used as cladding.

Several proposals for processing mercury-containing material in indirectly heated furnaces have been made, and patents have been issued [13-15].

The subsequent condensation of mercury from the furnace off-gas is treated in Section Condensation of Mercury from Furnace Off-Gas.

4.2. Extraction from Secondary Sources

Because of the relatively high toxicity of metallic mercury and some of its compounds, spent products must be reprocessed to a large extent. Storage of slurry-like residues is complicated and expensive, and is governed by the limited storage capacity of the closed mines. Active carbon slurries from the effluent concentration resulting from chlor – alkali electrolysis constitute the major proportion of mercury residues that must be reprocessed.

In addition to these residues, the processing of fluorescent bulbs, which contain about 15 – 50 mg of metallic mercury per lamp, is becoming increasingly important. Several plants dealing specifically with the disposal of these lamps already exist in the Federal Republic of Germany [16].

The mercury content of normal zinc – manganese dioxide batteries has been reduced considerably over the last few years (addition of mercury inhibits the formation of gas by zinc). In the Federal Republic of Germany, the mercury content of batteries will be reduced to 0.15 % by 1990 (Fig. 1), starting from a level of 1 % [17].

Figure 1. Reduction of mercury in primary batteries in the Federal Republic of Germany [17]

a) Mercury in sold primary batteries; b) Mercury in domestic refuse

In addition to zinc – manganese dioxide batteries, zinc – mercury(II) oxide batteries are also widely used as round cells. These contain ca. 30 % mercury, which must be recovered. Mercury in concentrations of ca. 1 % is also found in zinc – silver (II) oxide and zinc – oxygen batteries. A particular problem in reprocessing batteries is grading and sorting the various types, which are inadequately identified and, in some cases, have the same external dimensions for different electrochemical systems. Treatment processes have been developed in Japan [18], the Federal Republic of Germany [19], [20], and other countries [21], which can remove mercury by treatment in rotary kilns or in a distillation chamber. The individual types of batteries do not have to be sorted beforehand, and a mixture of batteries can be processed.

Because batteries also include a large number of plastics (e.g., as sealants), waste gases must be treated and burned if necessary.

Because a proportion of spent batteries end up in domestic refuse, high mercury concentrations can be found in waste gas from domestic refuse combustion. Mercury-containing older printing inks are another source. Because mercury can be precipitated from waste gas most efficiently by adsorption on activated carbon or similar substances, mercury-containing charcoal from waste gas purification will also require reprocessing in the future.

The mercury – selenium residue formed in the primary smelting of mercury-containing sulfidic ores requires special reprocessing. This substance, which occurs as a slurry, has been reprocessed in a multiple-hearth furnace in which the mercury fraction is evaporated [22]. Another company converts the residue to metallic mercury in a rotary kiln by adding lime fluxes, with a relatively inert residue remaining behind [23]. A hydrometallurgical reprocessing treatment has been investigated on a pilot scale in a research project [24]. Mercury is extracted in the form of mercury(II) oxide and sulfide, and can be added to the conventional extraction processes. The method does not appear to be economically practical at present

because of the relatively expensive reactants involved.

Additional secondary sources, such as thermometer breakage, electric switches, and amalgams, can generally be worked up by conventional distillation methods [25], [26]. A comprehensive monograph on the topic of evaporation and thermal dissociation of mercury sulfide is available [27]. Electrolysis has been proposed for the removal of mercury from gold-containing solutions: 90 – 95 % mercury and < 10 % gold are deposited at 1.0 – 1.5 V [28].

4.3. Condensation of Mercury from Furnace Off-Gas

The vapor pressure *p* (mbar of mercury) can be calculated according to a relationship given by BARIN and KNACKE [29]:

$$\log\ p = -\frac{3305}{T} - 0.795 \cdot \log\ T + 10.47983$$

where *T* is measured in kelvin.

The degree of saturation *s* (kg of mercury per cubic meter) of the gas at *t* (°C) or *T* (K) and *p* = 101.3 kPa can be determined from the pressure and density of mercury vapor (3.9091 kg/m^3 at 357 °C) (α = 1/273):

$$s = 3.9091 \frac{1 + 357 \cdot \alpha}{1 + \alpha t} \cdot \frac{p}{101.3} = 3.9091 \cdot \frac{630}{T} \cdot \frac{p}{101.3}$$

The degree of saturation *s* of mercury vapor calculated according to this formula for different temperatures is summarized in Table 6. Figure 2 shows *p* and *s* plotted as a function of 1/*T* on a semilogarithmic scale.

Table 6. Saturation content of mercury vapor at various temperatures

p, kPa	*T*, K	Saturation content *s*,	
		g/m^3	g/m^3(STP)
7.03×10^{-5}	283	0.00604	0.00626

101.3	630	3909.1	9021.1

Figure 2. Vapor pressure *p* and saturation content *s* (g/m^3) as a function of temperature; s_s saturation content under standard conditions [g/m^3 (STP)]

Mercury losses during condensation can be calculated as follows: 1 m^3 of saturated vapor at 140 °C (413 K) enters the condensation unit laden with 14.464 g of mercury. There it is cooled to 20 °C (293 K) (*s* = 0.0141 g/m^3), and a volume contraction to 293/413 = 0.71 m^3 occurs. The saturated vapor leaving the unit therefore contains 0.71×0.0141 = 0.01 g of mercury. The loss of uncondensed mercury removed with the waste gas is thus 0.07 % of the initial amount. With a

condensation end temperature of 40 °C and otherwise identical conditions, the loss increases to 0.35 % Hg.

In practical operation the mercury content in the hot reaction waste gases is always far below the saturation limit because the theoretical vapor – liquid equilibrium is not reached. Directly heated mechanical roasting furnaces require a heat input of ca. 1.2×10^6 kJ per tonne of ore. The following amounts of waste gas [in m^3 (STP)] are produced per 1000 kJ for the different fuels with 20 % excess of air:

Wood	0.387
Generator gas	0.42
Oil	0.32

Per tonne of ore, this corresponds to about 470 m^3 (STP) with wood or generator gas firing and 375 m^3 (STP) with oil firing. With 5 % water content in the ore, 70 m^3 (STP) of steam is produced in addition. If an ore containing 0.3 % Hg is worked up, the mercury content with wood or gas firing is 5.56 g/m^3 (STP), and with oil firing 6.75 g/m^3 (STP), at 140 °C.

With a condensation end temperature of 20 °C—at which the gas still contains 0.0141 g of mercury per cubic meter corresponding to the saturation limit—a loss of 0.21 – 0.25 % mercury occurs, and at a condensation end temperature of 40 °C, a loss of 1.1 – 1.3 % mercury from the waste gas occurs.

In general, the mercury residual content in waste gas, compared to the amount at 20 °C, increases with a temperature increase of

10 °C by a factor of 2.2
20 °C by a factor of 4.7
30 °C by a factor of 9.4
40 °C by a factor of 18.1
50 °C by a factor of 33.4

Thus efficient cooling of the waste gas is necessary. In a plant that processes an ore with 5 % moisture content, as much as 50 % of the cooler capacity is used for condensation of evaporated moisture alone, without the steam originating from fuel combustion being taken into account.

Several practical requirements must be met for satisfactory operation: (1) The ore should be as dry as possible. (2) The amount of waste gas produced by the fuel should be low. (3) When the gas enters the condenser, its temperature should be only 10 – 20 °C above the mercury dew point. (4) The outlet temperature should be as low as possible. (5) Before entering the stack, the reaction gas should pass through an afterpurification section, if possible. Stupp formation can be kept low by (1) indirect heating, (2) separate processing of fine-grain classes of ore, (3) predrying of ore that is too wet, or (4) wetting of ore that is too dry. The flue dust should be separated as completely as possible from the still hot reaction gas before it enters the mercury condensation unit.

A conveniently arranged condensation system for a *directly heated* mercury smelting plant operating with mechanical roasting furnaces consists of the following parts:

1. Dust separator in the form of a cyclone, an electrostatic precipitator, or a combination of both
2. Fan (e.g., of Monel Metal)
3. Cooling unit for mercury condensation
4. Afterpurification chamber for separating mercury residues
5. Injection chamber for separating traces of mercury
6. Fan (e.g., of Monel Metal)

The cooling unit is itself in many cases also constructed of monel metal, and consists of tubular condensers (CERMAK type) formed from six to ten trains arranged in parallel, each with eight inverted U-tubes of elliptical cross section whose arms terminate in acutely tapering, water-filled deflection boxes. The tubes are sprinkled with water. The mutually corresponding tubes of all the individual trains in each case end in a common box, and in this way the stupp can be classified. Gate valves in each train enable the draft to be regulated or even permit the train to be separately disengaged.

The ratio of tube cross section to fan output must be matched so that the gas flow velocity is maximally 0.75 m/s in narrow parts of the tubular condenser. The overall unit must be designed so that half of the tube trains can be decommissioned for cleaning and repair, whereas the remaining tube trains ensure satisfactory cooling of the reaction gas while maintaining draft conditions in the furnace.

Gases from *indirectly heated furnaces* that contain only a small amount of flue dust can be condensed by spraying water directly into the mercury-containing waste-gas stream. To ensure sufficient mercury condensation, the gas must pass through a succession of water curtains. Fewer parallel tubes of larger diameter are used in the cooling unit for directly heated furnaces. The last stage operates with fresh water; for the other cooling stages, water is circulated and recycled through suitably dimensioned settling tanks.

All settling tanks within the condensation unit have sloping floors and connecting pipes through which mercury metal flows to the lowest part of the system. The tanks stand on feet on a smooth cement floor, which slopes so that any leakage can be detected and escaping mercury collected. The material for these tanks is wood or cast iron; stupp-collecting tanks are also

constructed of concrete. When the plant is operating continuously, all places prone to thick deposits must be mechanically cleaned once a week; the remaining areas can be cleaned at longer intervals.

4.4. Treatment of the Stupp

The amount of mercury contained in the stupp may represent a substantial proportion of production. In Idrija, when processing high-bituminous ore, for example, 78 – 91 % of the mercury is extracted from the stupp and only 9 –22 % is extracted directly. To extract mercury from the stupp, individual mercury droplets must be coagulated, which can generally be achieved by kneading and pressing the mass. Stirring the stupp with sievelike perforated rakes in iron vessels also gives good results. Addition of quicklime to the stupp neutralizes any acids contained in the condensate, saponifies any fats present, absorbs a large proportion of the water, and chemically reduces mercury sulfate.

Mercury and dust can also be mechanically separated by simple wash treatment with water. A tenfold mercury enrichment from the stupp by *flotation* was described in 1929 [30]. This very effective method of separating mercury enables the waste material to be dumped directly onto the waste tip in certain cases. Generally, however, extraction of mercury from the stupp is not so effective, with the result that the low-mercury fraction must be returned to the smelting process. For regularly occurring large amounts of stupp, a special furnace unit is worthwhile (retorts or multiple-hearth furnace).

[Top of Page]

5. Environmental Protection

Matthias Simon

5.1. Natural Distribution of Mercury

Because of its high vapor pressure, metallic mercury disperses relatively quickly into the atmosphere and, with suitable air movement, is taken up by plants and animals. The average concentration in the earth's crust is 0.08 ppm and in seawater 3×10^{-5} ppm. Mercury is thus one of earth's relatively rare elements. The natural mercury content of the atmosphere is 0.005 – 0.06 ng/m^3 [31] ; in plants, 0.001 – 0.3 µg/g (generally < 0.01 µg/g) ; and in meat, 0.001 – 0.05 µg/g [32]. A comprehensive list of mercury in the environment appears in [33].

A quantitative summary of the occurrence, distribution, and utilization of mercury is given in the following material [34]:

Mercury content of the oceans	70 000 000 t
Mercury content of the earth's crust (1-m-thick layer)	100 000 000 t
Natural atmospheric mercury emission (volcanoes, wind erosion, degassing)	25 – 100 000 t/a
Natural mercury emission in water (weathering in rivers)	5000 t/a
Use of fossil fuels (minerals, deposits)	8 – 10 000 t/a
Use of mercury and its compounds	6000 t/a

Natural air emissions from mechanical activity, wind erosion, and degassing constitute the largest proportion of emitted mercury. By contrast, the utilization of mercury is relatively small, although this should not minimize or obscure the danger of mercury at high concentration.

5.1.1. *Mercury in Soil, Plants, and Animals*

Relatively large amounts of mercury are circulated due to the constant exchange of mercury among water, soil, and the atmosphere. Some of this migrating mercury is retained in the soil in the form of humus compounds and, in certain cases, is also concentrated [35]. The mercury content of various soils in Austria unless otherwise stated (mg per kilogram of soil) is as follows [36], [37]:

Meadowland in Niederösterreich	0.039
Arable land in Niederösterreich	0.180
Vineyards in the Burgenland	0.080
Reed belt on the Neusiedlersee	0.340
Arable land (3 % humus) in Kremsmünster	0.065
Meadowland (4.8 % humus) in Kremsmünster	0.070
Woodland (10.2 % humus) in Kremsmünster	0.170
Garden soil in England	0.25 – 15.0

Rice field slurry in Japan	0.40 – 1.8
Fields for agricultural use in Niedersachsen, FRG	0.055 – 0.104
Woodland in Niedersachsen, FRG	0.249 – 1.672
Mean mercury value for Europe (10-cm-thick humus layer)	120 g/ha

Organically bound mercury is also added to the soil with seeds as a seed treatment agent (fungicide). Amounts of mercury used for seed treatment or soil disinfection are as follows:

Grain (wheat) added as seed treatment agent to the soil per 150 kg of seed material/ha	ca. 7 g/ha
Sugar beet (seed material in pill form) added as seed treatment agent to the soil per 200 000 pills/ha	ca. 1 g/ha
Cotton (seed treatment and disinfection)	ca. 20 g/ha
Lawns (disinfection)	ca. 80 g/ha

However, neither soils that have received mercury-treated seeds for many years, nor plants grown on such soils, exhibit a high mercury content [35]. As pot tests have shown, the mercury is partly retained in the humus and partly evaporates from the soil [38], [39]. The amount of residue passing into groundwater is insignificant [40] (see Fig. 3).

Figure 3. Microcirculation of mercury (in g ha^{-1} a^{-1}) in the soil [36]

According to investigations carried out in Norway, the mercury content of soil varies between 0.022 and 0.55 ppm (mean value 0.19), without any “recognizable” effect due to human activity [41]. The mercury content in soil is higher in geothermal or ore-containing regions and can be as high as several parts per million. Thus, mercury is often used as a tracer metal in geological exploration [42].

Mercury content has been investigated in soil and lichen in the mercury mining region around Monte Amiata (Italy). The mercury content in the soil and in the lichen decreases sharply with increasing distance from the mine. Mine waste gases and worked ore are the main sources of emission [43].

Mercury in Fungi and Mushrooms. The fleshy parts of fungi and mushrooms can contain unexpectedly high concentrations of mercury [44], [45]. Because of the affinity of mercury for the sulfur-containing constitutents of fungi, the latter can absorb and concentrate mercury from the local soil. Mercury-rich fungi and mushrooms are found everywhere, regardless of whether the soil has been anthropogenically contaminated [46]. With more serious contamination, especially atmospheric, the mercury content of fungi and mushrooms increases considerably [47].

Mercury in Fish and Seals. The mercury content in *fish* varies depending on type and habitat [48]. The assumption that fish concentrate mercury to 2000 times its concentration in the ambient medium is neither valid nor statistically relevant and has no significance as a rule of thumb [48]. Mercury uptake in warm tropical waters is higher than in cold northern waters [49]. Because of the concentration of mercury in sediment, dabbling fish, which collect their food from the bottom of the water, absorb more mercury than nondabbling fish. Predatory fish (e.g., pike) contain higher than normal levels of mercury only if they preferentially feed on dabbling fish (see also Section Mercury in Food).

The controversy surrounding canned tuna in the United States has revealed that tuna preparations in the Smithonian Institute from ca. 1880 have the same mercury concentration as present-day fish. Under the assumption that the values found in museum preparations constitute a lower limit—some of the mercury might well have evaporated over the course of time—the fact that present-day values are the same as previous values means that no concentration has occurred.

Data from the Danube upstream of large cities and industrial regions, where trout have been found with a mercury content of > 1 mg of mercury per kilogram of fish, point to factors other than industrialization. The high mercury concentration in the liver of seals in the northern section of the east coast of North America (Labrador), where no large cities or industrial regions are to be found, is attributed to underwater volcanic emissions.

5.1.2. *Mercury in Food*

Many investigations were carried out on foods from the 1920s and 1930s onward [50]. In the Federal Republic of Germany, the Zentrale Erfassungs- und Bewertungsstelle für Umweltchemikalien (central office for collecting and evaluating data on environmental chemicals; ZEBS) of the Federal Ministry of Health in Berlin in particular, has collected data from 1975, 1979, and 1982. According to these data, if average consumption patterns are assumed, mercury uptake in 1979 was about 0.052 mg per week for the “average” inhabitant of the Federal Republic of Germany (i.e., only about one-sixth of the upper limit recommended by WHO). The major proportion of mercury is absorbed from animal foods [51]. The legal limits are given in Table 7.

Table 7. Legal limiting values for total uptake of mercury (1980)

	Fish, mg/kg	Total uptake, mg/week
Switzerland	0.5	
Japan	0.4 (Hg)	0.17 mg of Hg per 50 kg of body weight
	0.3 (Hg methyl)	
United States	1.0	0.005 mg/kg of body weight (Hg)
		0.0033 mg/kg of body weight (Hg methyl)
Sweden	no limit (lakes that contain fish with more than 1 ppm Hg are placed on a blacklist) ; fish with a high Hg content may be legally rejected.	
Federal Republic of Germany	1.0	0.3 (max.)
WHO recommendation		

The ZEBS investigations [52] covering 1978 – 1982 are presented in Tables 8 and 9. The 1982 values essentially confirm the analytical data of 1979. The values for milk, condensed milk, cheese, and eggs; veal, beef, pork, calves liver, calves kidneys, poultry, sausages, and meat products; vegetable oils and fats; rice, rye, and potatoes; leafy, sprouting, fruit, or root vegetables and canned vegetables; pomaceous, stone, berry, citrus, shell, or canned fruit; fruit and vegetable juices; and beverages such as wine, beer, and chocolate are all < 0.020 mg of mercury per kilogram of fresh substance and, in most cases, < 0.010 mg/kg.

Table 8. Mercury in food

Food	Content, mg/kg of fresh substance	
	1982	1979
Cow's liver	0.021	0.015
Pig's liver	0.047	0.058
Cow's kidneys	0.077	0.066
Pig's kidneys	0.246	0.260
Freshwater fish	0.271	0.257
Saltwater fish, except Hg-susceptible fish	0.196	0.127
Hg-susceptible fish*	1.070	0.859
Fish products	0.208	
Canned fish	0.206	0.188
Wheat	0.026	0.003
Coffee	0.041	

* Hg-susceptible fish include: mackerel shark, dogfish, blue ling, halibut, black halibut, turbot, and Greenland shark.

Table 9. Uptake amounts of mercury in absolute figures and as a proportion of WHO values

	Hg
WHO value	
mg/week (70 kg)	0.35
mg/week (58 kg)	(0.290)
Men (70 kg)	
mg/week*	0.1229
Proportion of WHO figure, %	35.11
Women (58 kg)	
mg/week*	0.0933
Proportion of WHO figure, %	32.17

* The median values of toxic substance levels were taken into account.

The average amounts of mercury actually absorbed per week are compared in Table 9 with the limiting values specified by WHO. Foods contain the major proportion as follows: drinking water (14.8 %), wheat (12.9 %), milk (10.2 %), mineral water (8.1 %), canned fish (8.0 %), coffee (7.2 %), potatoes (6.0 %), and fish (5.6 %). Another detailed investigation carried out by ZEBS is concerned with the mercury, magnesium, and zinc content of breast milk, blood serum, and the fatty tissue of nursing mothers [53].

5.2. Mercury Emissions

5.2.1. *Gas Purification*

In a large number of combustion processes, mercury is transferred to the gaseous phase and must be removed again by subsequent treatment. The largest amounts of secondary mercury occur in the smelting of sulfidic ores. Mercury which is present as mercury sulfide is released during roasting. At present, two methods are primarily used for waste-gas purification.

In the first method, the gas is treated with sulfuric acid (90 %) at 200 °C. The mercury(I) sulfate formed is deposited in wash towers. Fine purification is performed by afterpurification with sodium sulfide [54]. In the second method, the cooled and dusted roast gas is treated with a mercury(II) chloride solution, and mercury precipitates as mercury(I) chloride (Hg_2Cl_2). Mercury is removed from the wash liquid by treatment with sodium sulfide. Part of the mercury(I) chloride produced is oxidized to mercury(II) chloride with gaseous chlorine and returned to the process. The final level of mercury in the waste gas is 0.05 – 0.1 mg/m^3 [55], [56].

In a third method, waste gas containing mercury and sulfur dioxide is treated with a wash solution containing Cu^{2+} and Hg^{2+} ions in addition to H_2SO_4 (200 – 300 g/L) and HCl (5 g/L). Mercury in the vapor is thereby oxidized to Hg^+, and the Hg^0 values of the waste gas are 0.02 –0.05 mg/m^3 [57].

Another source of mercury emission is refuse combustion. Mercury occurs in the form of thermometer breakage, fluorescent tubes, switches, and batteries in domestic refuse. Investigations have shown that mercury in flue gases is present as mercury(II) chloride [58]. Below ca. 150 °C, the flue ash contained in flue gases adsorbs mercury(II) chloride and reduces it to mercury(I) chloride. Active carbon or active carbon impregnated with iodine compounds can also be used as a mercury adsorbent [59-62]. The mercury content of domestic refuse is 3 – 5 g/t [63]. The percentage distribution of mercury in a typical refuse combustion plant is shown schematically in Figure 4. Most of the mercury passes into the residue to be dumped.

Figure 4. Specific mercury load distribution in the Bamberg refuse heating and power station with TMT-15 precipitation, with and without sludge combustion [63]

5.2.2. *Water Purification*

The solubility of mercury in water depends strongly on the temperature (see Section Physical Properties). It decreases with decreasing temperature and can be reduced further by addition of salts (e.g., sodium chloride).

A whole range of equipment and devices can be used in purification methods to remove mercury from water. Examples are activated carbon filters, ion exchangers, and electrolysis systems. Mercury can also be removed from solution by addition of suitable reagents.

The level of 10 – 30 mg of mercury per liter in wastewater from chlor – alkali electrolysis can be reduced to 0.1 mg/L by using *activated carbon* and graphite powder. The carbon has a grain size of 5 – 100 µm [64], [65]. In principle, all types of activated carbon can be used for the fine purification of mercury-containing water. Carbon is dispersed in the water and then filtered.

For *ion exchangers,* a distinction can be made between reusable and disposable ones [65-67]. In some cases, sulfur-containing substances are used as active groups, which remove mercury from the solution in the form of a mercury sulfide compound.

Copper fluidized-bed electrolysis provides another method for mercury separation. The copper powder cathode is held in suspension by the flowing solution, and mercury is deposited as an amalgam. The copper amalgam is purified by distillation [68].

By adding *small amounts of oil* which are dispersed in the aqueous solution, mercury can be concentrated in the oil phase. The mercury content of the purified aqueous solution is in some cases < 10 µg/L. The oil is separated by centrifugation, and fine purification is carried out by using a conventional oil – water emulsion splitting unit. The initial mercury concentration should be between 0.5 and 2.0 mg/L [4]. Tin(II) chloride dissolved in dilute hydrochloric acid has been proposed for treating mercury ion-containing wash water from combustion units. The reducing agent tin(II) chloride is added in above-stoichiometric quantities. Reduced mercury is added together with the wash water to an evaporation device and is expelled by passage of stripping gas at elevated temperature. Condensation is effected by cooling the gas stream. The mercury content is thus reduced from 5 mg/L to < 0.1 mg/L, depending on the concentration of tin(II) chloride [69].

To purify flue gas wash water from *refuse combined heating and power stations,* the additive TMT-15 developed by Degussa is used in some cases on an industrial scale (see Fig. 4). The active substance of the additive consists of trimercapto-*s*-triazine in the form of a sodium salt. Mercury is bound as $C_6N_6S_6Hg_3$. The compound is stable up to 210 °C and is only sparingly soluble in the elution test (a test to determine the soluble components of a solid material). The mercury content is reduced from ca. 4 mg/L to < 0.05 mg/L [70], [71]. The additional costs involved in TMT-15 precipitation amount to ca. 0.25 DM per tonne of refuse.

Mercury can be removed from *concentrated sodium hydroxide solution* by the use of ultrasound when the solution is filtered. The initial mercury content of ca. 20 mg/kg of aqueous sodium hydroxide is reduced to ca. 0.4 mg/kg after filtration [72].

The fine purification of *crude phosphoric acid* can be performed at pH 0.5 – 1.5 by using a diorganodithiophosphorus compound in conjunction with activated carbon as adsorbent. The final mercury concentration is < 0.02 µg/g of solution [73]. At present, no standard methods exist for removing mercury from sulfuric acid [74].

[Top of Page]

6. Quality Specifications

Matthias Simon

Fine Purification of Metallic Mercury [75]. Most of the mercury on the market is 4N material (99.99 % mercury). Higher purity is seldom required. Impurities in the form of gold (> 10 ppm) are manifested as dark particles after dissolution in nitric acid. Only a few purification methods exist.

1. *Dry Oxidation.* In this method, readily oxidizable constituents such as magnesium, zinc, copper, aluminum, calcium, silicon, and sodium can be removed by passing air or oxygen through the liquid metal. The oxides formed have a lower density than mercury and float on its surface. They can be removed by filtration, scooping, or withdrawing the mercury through an opening in the bottom.
2. *Wet Oxidation.* In an aqueous medium, mercury is dissolved by adding nitric, hydrochloric, or sulfuric acid with dichromate, permanganate, or peroxide, to oxidize impurities. Good dispersion of the mercury is extremely important in this method. The aqueous solution can be separated from the mercury by decanting, and traces of water can be removed with calcium oxide. A plant for the wet purification of mercury has been described [76].
3. *Electrolytic Refining.* Perchloric acid containing mercury oxide serves as the electrolyte.
4. *Distillation.* Mercury can be evaporated under atmospheric pressure or in vacuo. Distillation can be carried out in normal steel vessels or in a glass apparatus. Elements with a lower vapor pressure than mercury can be separated in this way. In many cases, mercury must be distilled repeatedly to achieve the desired purity, particularly if it is to be used to produce cadmium – mercury telluride.

Additional methods, adapted to the relevant processes, are available for purifying and working up larger amounts of mercury [77], [78].

[Top of Page]

7. Chemical Analysis

Matthias Simon

The oldest and simplest method for determining mercury in minerals is described by ESCHKA ; it involves a gravimetric method in which mercury is precipitated as an amalgam [79]. The ore sample is weighed in a porcelain crucible, intimately mixed with iron filings, and then covered with a layer of zinc oxide, magnesium oxide, or calcium oxide. The crucible is closed with a tightly fitting cover of gold foil having a cup-shaped depression in the middle, which is sprayed from above with cooling water. On careful heating of the sample, mercury is distilled and deposits on the underside of the cover. When a constant weight is reached at the gold foil, all the mercury has been collected. Measurements can be affected by cadmium and arsenic, which also condense on the gold foil. This method of mercury determination requires a high level of experimental skill and care on the part of the analyst, whose technique greatly affects the accuracy and reproducibility of the results. The reliably detectable minimum mercury content is between 10 and 50 ppm. Theoretically, the accuracy could be improved by increasing the amount of sample, although this would give rise to difficulties with regard to the apparatus.

A method for precipitating *monovalent* mercury as an iodate from a neutral or weakly acidic solution (nitric acid) is described in [80]. Mercury can be determined gravimetrically after the mercury(I) iodate precipitate is washed with ethanol and diethyl ether. Parallel gravimetric determination of the excess of potassium iodate precipitation agent is possible with thiosulfate after the mother liquor has been acidified with sulfuric acid and potassium iodide has been added. Both methods give good results.

A quick method for determining *mercury*(*II*) is based on the fact that a complex is formed when an excess of potassium iodide is added to a neutral or weakly ammoniacal mercury solution. This complexes with copper diethylenediamine sulfate to form violet crystals of the complex double salt copper diethylenediamine mercury iodide, which is practically insoluble in ethyl alcohol or diethyl ether [81].

In a rapid classical qualitative method for detecting mercury, ca. 1 g of the substance to be tested is digested with acid; the resultant solution is oxidized with a drop of bromine (the solution must not turn yellow) and then boiled with a few milliliters of the reagent (10 g of KI and 100 g of NaOH in 100 mL of H_2O) and filtered. In the filtrate, mercury is determined by the black precipitate formed on dropwise addition of a Sn^{2+} solution [82].

Modern operational monitoring employs physical analytical methods and test tube methods suitable for quick detection. Both *X-ray fluorescence spectroscopy* (XRF) and *atomic absorption spectroscopy* (AAS) have proved suitable for quantitative and qualitative mercury determination. The detection limit for these methods is so low that the maximum workplace concentration values can be monitored precisely [83].

Portable atomic absorption spectrometers, for example, are available, which indicate the atmospheric mercury concentration as an analog or digital display after a short warm-up time of the spectrometer. The result of the analysis is available immediately and simplifies the monitoring of a production plant. The measurement value can also be recorded continuously at stationary measurement sites with a recorder. The influence of interfering factors in AAS determination is discussed in [84].

Differential pulse anodic stripping voltammetry (DPASV) in conjunction with a gold electrode can be used to detect copper and mercury in natural water and wine [85], [86]. A mercury concentration of 0.02 µg/L can be measured.

Mercury in the air can be detected down to 0.1 ng/m^3 with the *Coleman mercury analyzer* system (based on a very selective cold vapor atomic absorption), to an accuracy of 10 %. One analysis takes about 3 min [83].

[Top of Page]

8. Storage and Transportation

Matthias Simon

A classification for the transportation of mercury, mercury oxide, mercury(I) chloride, and mercury(II) chloride is given in [87] (specification sheets 831, 863, 865, 868). DORIAS presents a detailed description of the properties, handling, storage, and transportation of dangerous substances [88], as well as a list of addresses of the relevant authorities (throughout Europe) for information purposes. The provisions differ from country to country and must be ascertained from the relevant authorities.

In general, containers of stainless steel, normal-quality steel, iron, glass, ceramics, and a range of plastics are suitable for storing mercury. When storing liquids that contain extremely low levels of mercury (µg/g – ng/g range) in plastic containers, mercury losses occur with a large number of plastics. When water containing 5 ng/g of mercury was stored in polyethylene bottles, only 5 % of the mercury was present after 21 d. Approximately 77 % of the mercury had been adsorbed on the side walls, and 18 % had evaporated. The Hg^{2+} ions are assumed to be reduced to Hg^{+} ions, which in turn disproportionate to Hg^0 and Hg^{2+} [89]. Addition of Au^{3+} ions in trace amounts is sometimes recommended [90]. Further investigations on the storage of mercury in dilute solution are discussed in [91-95].

[Top of Page]

9. Uses

Matthias Simon

Because of its special properties, mercury has had a number of uses for a long time. The conventional application is the thermometer. Mercury is frequently used in pressure gauges and for thermal content measurements.

In mechanical engineering, mercury is used in mercury vapor diffusion pumps for producing a high vacuum.

One important area of use is the lighting industry, where mercury is added to various types of bulbs. Among electrical components, mercury switches, rectifiers, oscillators, and primary batteries can be mentioned, which contain up to 30 % mercury.

Mercury is used as a liquid cathode in the production of chlorine and sodium hydroxide by chlor – alkali electrolysis. Because mercury forms alloys with a large number of metals, mercury alloys have a wide range of applications. Table 10 summarizes the areas of use of mercury and its compounds.

Table 10. Uses of mercury and its compounds [96]

Area of use	Form	Approximate	Emissions	Other	Remarks

		amount, t/a		sectors, waste elimination	
Chemicals, reagents	compound	40	laboratories		largely impossible to find suitable replacement; environmental damage can be reduced by other measures
Alkali – manganese batteries	chloride/metal	37		refuse combustion	reduced emission by separate collection possible
Mercury oxide batteries	oxide	20		refuse combustion	alternatives still too expensive; separate collection declining
Pesticides		27	distribution		now only for seed treatment; substitutes are available
Medicinal sector		26		refuse combustion	separate collection possible
Dental amalgams	metal				
Disinfection	compound				
Fungicides for paints	compound	10	weathering	exploitation; removal of old paint coats	declining; in some cases restrictions on use
Catalysts	compound	8		chemical industry	declining
Thermometers, barometers, manometers	metal	8	instrument and apparatus breakage	refuse combustion	replacement by other methods and processes possible (e.g., electronics)
Electrical engineering components	metal	6		refuse combustion	declining; substitution possible largely through electronic components
Interval switches				exploitation of scrap	
Fluorescent tubes	metal	3	lamp breakage	refuse combustion	demand for fluorescent tubes increasing, despite reduction in mercury use per tube; total use increasing
Pigments	sulfide	1		refuse combustion	declining

[Top of Page]

10. Mercury Alloys

Matthias Simon

10.1. General

The alloys of mercury (amalgams) occupy a special position among metal alloys because they can be solid, plastic, or liquid at room temperature.

Liquid amalgams are true solutions of the alloying elements in mercury, whereas *plastic* amalgams are suspensions of solid particles of the alloying partners in mercury or a saturated mercury solution. *Solid* amalgams are intermediary phases, often mixed with alloying partners or their primary mixed crystals. Solid amalgams may contain liquid-phase inclusions. An amalgam is sometimes difficult to identify experimentally. JANGG has suggested a suitable apparatus for synthesizing and

analyzing amalgams [97].

The solubility of many metals in mercury depends strongly on temperature (see Fig. 5). The solubility of some metals in mercury at room temperature is given in Table 11. Amalgam formation may be exothermic (e.g., sodium) or endothermic (e.g., gold).

Table 11. Solubility of some metals in mercury at 20 °C [97]

Metal	Solubility, %	Metal	Solubility, %
Tl	42.5	Mg	ca. 0.3
Cd	5.0	Au	0.131
Zn	1.99	Ag	0.035
Pb	1.47	Cu	ca. 0.002
Sn	ca. 0.9	Al	0.002
Na	0.62	Fe	ca. 10^{-5}
K	ca. 0.4	Si	virtually insoluble

Figure 5. Solubility of some metals in mercury as a function of temperature [99]

Ammonium amalgam, which has been known for a long time, is an interesting case of the NH_4 group acting as a metal-like alloying constituent. The synthesis of tetramethylammonium amalgam is described in [98].

Technically important amalgams are those of tin – copper – precious metals used in conservative dental treatment.

Gold, silver, or tin amalgams are still used for much gold- and silver-plating work, as well as for production of certain types of mirrors. The measurement range of mercury thermometers can be extended to – 58 °C by addition of thallium to mercury.

Alkali amalgam is an important intermediate in chlor – alkali electrolysis by the amalgam method. Amalgams also play a role in the extraction of cadmium or aluminum [99].

A comprehensive list of thermodynamic data on amalgam formation has been collected by GUMINSKI [100]. After surveying the literature, he is of the opinion that liquid mercury greatly influences intermetallic compound formation. The reactions are comparable to the solid-state formation of ionic and nonionic substances in liquids.

10.2. Production of Amalgams

Three methods are used for the industrial production of amalgams:

1. *Powder Metallurgy Method.* The powdered alloying components are mixed with mercury. The reaction rate of spontaneously occurring amalgam formation is determined by the degree of dispersion of the powder, the rate at which reactants diffuse into one another, and the wettability of the powder by liquid mercury. If other components besides mercury are added simultaneously, they are preferably pulverized as master alloy in the desired weight ratio. In many cases, the powder reacts with mercury more quickly in the presence of a salt of the element to be amalgamated.
2. *Galvanic Amalgam Formation.* Many metals can be deposited from their aqueous solutions or from salt melts on mercury cathodes, with simultaneous formation of an amalgam. Because of the high overvoltage of hydrogen on mercury or amalgam cathodes, even nonprecious metals (Zn, Fe, Mn) can be deposited from acid solutions. Nonaqueous solutions may also be used (with Mg, Ti).
3. *Reaction with Sodium Amalgam.* Metal exchange can occur in a fast and stoichiometric reaction through the phase boundary by reaction of sodium amalgam with the salt solution of a precious metal (or, generally, by reacting a nonprecious amalgam with a noble-metal salt solution).

[Top of Page]

11. Mercury Compounds

Gabriele Wühl-Couturier

11.1. Inorganic Compounds

Mercury occupies a special position in group 12 of the periodic table. In contrast to the two other members of this group (zinc

and cadmium), it forms compounds in two valence states.

Compounds of *monovalent* mercury contain ions in the unusual form Hg_2^{2+}. These compounds are not very stable and disproportionate easily to form elemental mercury and the corresponding divalent mercury derivative. Most of the monovalent compounds are sparingly soluble in water. The more soluble salts, e.g., the nitrate, are partially hydrolyzed in aqueous solution: after acidification of these solutions, the poorly soluble compounds can be obtained by precipitation. In addition, compounds of monovalent mercury can be prepared from those of the divalent element by reduction with metallic mercury.

The compounds of *divalent* mercury can be divided into those that are strongly dissociated and those that are weakly dissociated. The former, such as the sulfate and the nitrate, undergo considerable hydrolytic cleavage in water. The weakly dissociated compounds, e.g., the chloride and the cyanide, are less prone to hydrolysis by water. With excess anions they form complexes that are more soluble than the salts themselves.

The starting material for all of these compounds is elemental mercury: the metal is treated initially with a suitable oxidizing agent, e.g., chlorine or nitric acid. The other compounds can be obtained from the resulting oxidation product by further reaction. Multistep processes are often necessary.

11.1.1. *Mercury Chalconides*

Chalconides of monovalent mercury are unknown: precipitation from a solution of mercury(I) nitrate with sodium hydroxide does not lead to the expected mercury(I) oxide, but rather to a mixture of finely divided elemental mercury and mercury(II) oxide. The chalconides of divalent mercury exist in nature as minerals: the oxide HgO as montroydite, the sulfide HgS as cinnabar and metacinnabar, the selenide HgSe as tiemannite, and the telluride HgTe as coloradoite. They can also be produced synthetically. Only the oxide and the sulfide are of practical importance.

Mercury(II) oxide [21908-53-2], HgO, M_r 216.59, ϱ 11.1 g/cm^3, is a red or yellow powder. The color depends on the size of the crystals: the yellow oxide consists of crystals < 2 µm; the red one of crystals > 8 µm in diameter. Samples with particle sizes between these two values appear yellow- to red-orange. Increasing the temperature leads to an intensification of the color: the yellow oxide becomes yellow-orange; the red one, dark red. The crystal lattice is rhombic and identical for both forms. Under certain preparative conditions a hexagonal form exists. This modification has no practical importance and can be converted to the more stable rhombic form by heating above 200 °C.

Heating above 450 °C causes the oxide to decompose into elemental mercury and oxygen. Mercury(II) oxide is sparingly soluble in water and in ethanol. With dilute mineral acids, solutions of the corresponding salts are formed, a method that can be used to prepare these salts.

Production. Mercury(II) oxide can be prepared via the *anhydrous route* by reaction of the elements at 350 – 420 °C under oxygen pressure or by thermal decomposition of mercury nitrates at ca. 320 °C. Production via the *wet route* by precipitation is more important: the oxide is precipitated from solutions of mercury(II) salts by addition of caustic alkali [usually mercury(II) chloride solutions with sodium hydroxide]. Whether the yellow or the red form is obtained depends on reaction conditions: slow crystal growth during heating of mercury with oxygen or during thermal decomposition of mercury(I) nitrate leads to relatively large crystals (i.e., the red form). Rapid precipitation from solution gives finer particles (i.e., the yellow form). Nevertheless, depending on the conditions during precipitation such as stirring speed, pH, temperature, and method of mixing the components, large crystals can be obtained by the wet route and, therefore, the red form is produced [101].

Uses. Red mercury(II) oxide in particular has become increasingly important for the production of galvanic cells with mercury oxide anodes in combination with zinc or cadmium cathodes. These cells are distinguished from other systems in that their voltage remains very constant during discharge; they are used mainly as small button-shaped batteries, e.g., for hearing devices, digital watches, exposure meters, pocket calculators, and security installations. Additional uses of mercury(II) oxide include the following: for the production of mercury(II) salts by treatment with the corresponding acids, and as a reagent in analytical chemistry. Its importance as an additive to antifouling paint for ships and in medicine (e.g., for eye ointment) has decreased.

Mercury(II) sulfide [1344-48-5], HgS, M_r 232.65, is the most important starting material for mercury extraction; it can exist in two forms: α-HgS (*cinnabar,* cinnabarite) has a density of 8.1 g/cm^3, and β-HgS (metacinnabar) has a density of 7.7 g/cm^3. The β-form slowly changes to α-HgS on heating. The latter sublimes at 583 °C. Of the two sulfide minerals, cinnabar is the most important ore for the production of mercury (see Production). When pure, the compound is bright red and forms hexagonal crystals. *Metacinnabar* is black and forms cubic crystals (zinc blende lattice). Both have extremely low water solubility; they are also insoluble in mineral acids and in caustic alkali. They dissolve only in aqua regia, to release sulfur, and in alkali sulfide solutions, to form thio complex-salt ions, such as $[HgS_2]^{2-}$.

Production by either the dry or the wet route is possible. In the former, a mixture of mercury and sulfur is heated. The elements react slowly together even on mixing. Production from aqueous solutions is more important. The sulfide is precipitated from solutions of mercury(II) salts by treatment with hydrogen sulfide, alkali, or ammonium sulfide solutions. Initially, the black sulfide is formed. It can be converted to the more stable red form by heating in the presence of the mother liquor or with ammonium polysulfide solutions. The reaction of mercury and sulfur by heating with a solution of sodium polysulfide has been described [102].

11.1.2. *Mercury Halides*

Halides of both mono- and divalent mercury are known. Of these, only the fluorides are ionic compounds: they undergo hydrolysis with water; mercury(I) fluoride simultaneously undergoes disproportionation. The other halides either are already composed of molecules in the crystal lattice or form these by dissolution or evaporation. Accordingly, their melting and boiling points are low. The halides of monovalent mercury are sparingly soluble in water: the solubility of divalent mercury halides

decreases with increasing molecular mass. Mercury halides form numerous basic compounds.

Mercury(II) fluoride [7783-39-3], HgF_2, M_r 238.59, *mp* 645 °C, ϱ 9.0 g/cm^3, forms colorless octahedral crystals with a cubic ionic lattice (fluorite type). It is unstable in humid air; hydrolysis yields a yellow color. Mercury(II) fluoride is insoluble in organic solvents.

The compound is *produced* from mercury and fluorine at elevated temperature or from mercury(II) oxide and hydrogen fluoride under oxygen pressure at 450 °C [103]. Synthesis from mercury(II) oxide and sulfur tetrafluoride has been suggested [104]. The compound is used in organic synthesis as a fluorinating agent.

Mercury(I) chloride [10112-91-1], calomel, Hg_2Cl_2, M_r 472.09, ϱ 7.15 g/cm^3, is rarely found as a mineral in nature. When pure, it exists as a heavy white powder or as colorless crystals with a silvery luster, having a tetragonal molecular lattice. It sublimes at 385 °C ; above 400 °C the molecules decompose into a vapor composed of mercury and mercury(II) chloride. The substance is sparingly soluble in water, ethanol, diethyl ether, and acetone. A black color occurs in ammonia solution, whereby a mixture of finely divided elemental mercury and mercury(II) ammonium chloride is formed by disproportionation—hence, the name *calomel*, from the Greek word meaning beautiful black.

Production. An intimate mixture of mercury and mercury(II) chloride is heated at 525 °C in closed iron or fused silica tubes, attached to cooled receivers in which calomel vapor condenses [105], [106]. Synthesis from the elements is also possible [101]. Very finely divided mercury(I) chloride can be obtained by precipitation from a dilute nitric acid solution of mercury(I) nitrate and sodium chloride [105].

Mercury(I) chloride finds *application* in calomel electrodes, which serve as standard electrodes for the measurement of electrochemical potential; it is also employed as a fungicide and insecticide in agriculture, and as a catalyst in organic synthesis. Mercury(I) chloride is mixed with gold for painting on porcelain.

Mercury(II) chloride [7487-94-7], corrosive sublimate, $HgCl_2$, M_r 271.50, *mp* 280 °C, *bp* 303 °C, ϱ 5.43 g/cm^3, is a white, heavy, crystalline powder with a rhombic crystal lattice. At the melting point the vapor pressure is 560 kPa; the substance can, therefore, sublime under reduced pressure. The sublimate is moderately soluble in cold water. Its solubility increases sharply with increasing temperature: the saturation limit is 6.2 % at 20 °C and 36.0 % at 100 °C ; the compound may therefore be purified by recrystallization from water. The sublimate is readily soluble in organic solvents, in contrast to mercury(I) chloride, so that a clear solution, for example, in ether, is an indication of the absence of calomel. Molecules of mercury(II) chloride exist as such in all solvents; mixing Hg^{2+} ions with Cl^- in aqueous solution leads immediately to undissociated mercury(II) chloride molecules; this process is used analytically to bind chloride ions in determining the COD of effluents. Aqueous solutions of sublimate are weakly acidic, resulting from hydrolysis of a small amount of the chloride. The sublimate is much more soluble in alkali chloride solution than in pure water, because of the formation of chloro complex ions, e.g., $[HgCl_4]^{2-}$.

Production. For the formation of mercury(II) chloride from the elements, mercury is oxidized with chlorine in heated retorts; the reaction is carried out with the appearance of flame at > 300 °C. The escaping sublimate vapor is condensed in cooled receivers, where it settles as fine crystals. Formation of mercury(I) chloride is avoided by the use of excess chlorine [101]. Mercury and chlorine also react in the presence of water; in this case, intensive stirring is necessary. The chloride formed precipitates as crystals after the solubility limit has been exceeded. If an alkali chloride solution is used in place of water, solutions of chloro complex salts are formed, which are used mainly for the production of other compounds of divalent mercury [107].

Mercury(II) chloride can also be prepared from other mercury compounds. Mercury(II) sulfate, for example, is heated in the dry state with sodium chloride, and the evolving mercury(II) chloride vapor is condensed to a solid in receivers. A warm sublimate solution is obtained from the reaction of mercury(II) oxide and a stoichiometric amount of hydrochloric acid; the chloride separates as crystals on cooling.

Uses. Mercury(II) chloride is an important intermediate in the production of other mercury compounds, e.g., mercury(I) chloride, mercury(II) oxide, mercury(II) iodide, mercury(II) ammonium chloride, and organic mercury compounds. The compound is used as a catalyst in the synthesis of vinyl chloride (⟶ Chlorinated Hydrocarbons – Vinyl Chloride from Acetylene), as a depolarizer in dry batteries, and as a reagent in analytical chemistry. It has minor importance as a wood preservative and retains some importance as a fungicide. Other uses (e.g., as a pesticide or in seed treatment) have declined considerably.

Mercury(II) bromide [7789-47-1], $HgBr_2$, M_r 360.41, *mp* 236 °C, *bp* 320 °C, ϱ 6.05 g/cm^3, forms colorless crystals with a rhombic layered lattice. Its water solubility is highly temperature dependent: the concentration limit is 0.6 % at 25 °C and 18 % at 100 °C. Mercury(II) bromide is readily soluble in diethyl ether and ethanol. The compound is *produced* from mercury and bromine in the presence of water; by dissolution of mercury(II) oxide in hydrobromic acid; or by precipitation from a nitric acid solution of mercury(II) nitrate with addition of sodium bromide [108]. It is *used* as a reagent for arsenic and antimony, as an intermediate in the production of bromine-containing organomercury compounds (see Organic Compounds), and as a catalyst in organic synthesis. The melt is used as a nonaqueous solvent.

Mercury(II) iodide [7774-29-0], HgI_2, M_r 454.45, exists in a red and a yellow form. *Red mercury(II) iodide* is soluble in diethyl ether, chloroform, and methanol. The compound is produced by adding an aqueous solution of potassium iodide to an aqueous solution of mercury(II) chloride with stirring; the precipitate is then filtered off, washed, and dried at 70 °C. A yellow product is formed by sublimation; on cooling, it turns red.

Yellow mercury(II) iodide, *mp* 259 °C, *bp* 354 °C, is unstable at room temperature and is converted to the red form at the slightest touch or upon heating. The transition temperature is 127 °C. Yellow mercury(II) iodide is prepared by pouring an alcoholic solution of the red form into cold water, whereby a pale yellow emulsion is formed, from which the mercury(II) iodide crystallizes after a few hours.

Potassium mercury iodide [7783-33-7], K_2HgI_4, M_r 786.45, readily soluble in water, is prepared by dissolving mercury(II) iodide in a concentrated potassium iodide solution.

11.1.3. *Mercury Pseudohalides*

The *cyanides* and *thiocyanates* of divalent mercury resemble the halides, in that they also exist in solution as undissociated molecules and form highly soluble complexes with an excess of the anion; moreover, numerous basic compounds are derived from them. Mercury(I) cyanide is unknown; the poorly soluble mercury(I) thiocyanate, which can be obtained by precipitation from mercury(I) nitrate solution, has no practical importance.

Mercury(II) Cyanide (⟶ Cyano Compounds, Inorganic – Cyanides of Mercury, Lead, Cobalt, and Nickel***)***

Mercury(II) thiocyanate [592-85-8], $Hg(SCN)_2$, M_r 316.75, ϱ 3.71 g/cm^3, is a white powder which is thermally unstable. Decomposition begins at 110 °C and becomes spontaneous at 165 °C, with the compound swelling to many times its normal volume. In air a blue flame appears, and a dark-colored, voluminous residue is left. The thiocyanate is sparingly soluble in cold water. It is produced by precipitation from mercury(II) nitrate solution with a stoichiometric amount of potassium thiocyanate solution and is used as an analytical reagent and as an intensifier in photography.

11.1.4. *Acetates, Nitrates, Sulfates*

The acetates, nitrates, and sulfates of mercury are composed of ions and undergo hydrolysis with water. The acetate and the sulfate of monovalent mercury are sparingly soluble and the nitrate is quite soluble in dilute acid. Compounds of divalent mercury are readily soluble in dilute acid.

Mercury(II) acetate [1600-27-7], $(CH_3COO)_2Hg$, M_r 316.68, ϱ 3.27 g/cm^3, *mp* 178 °C, exists as a fine white powder or colorless shiny crystal flakes. It is soluble in diethyl ether and ethanol. It is produced by dissolution of mercury(II) oxide in dilute acetic acid and concentration of the resulting solution. Mercury(II) acetate is used for the synthesis of organomercury compounds, as a catalyst in organic polymerization reactions, and as a reagent in analytical chemistry.

Mercury(I) nitrate [10415-75-5], $Hg_2(NO_3)_2 \cdot 2\,H_2O$, M_r 561.22, ϱ 4.68 g/cm^3, *mp* 70 °C, which forms colorless crystals (monoclinic ionic lattice), is produced by dissolving mercury in cold dilute nitric acid and crystallizing the compound from the resulting solution.

Uses. Mercury(I) nitrate is the most readily available soluble salt of monovalent mercury and is, therefore, an important intermediate for other mercury(I) derivatives; sparingly soluble compounds can easily be prepared from it by precipitation from aqueous solution. Thermal decomposition leads to red mercury(II) oxide. “Millons reagent,” a solution of mercury nitrate and nitrous acid in dilute nitric acid, is used as an analytical reagent for the indication of tyrosine-containing proteins.

Mercury(II) nitrate [10045-94-0], $Hg(NO_3)_2$, M_r 324.60 ; $Hg(NO_3)_2 \cdot H_2O$, M_r 342.62, forms colorless, hygroscopic crystals. Apart from the anhydrous salt and the monohydrate, several other hydrates and basic compounds are known. Mercury(II) nitrate is produced by dissolving mercury in hot concentrated nitric acid; the resulting solution is concentrated and the nitrate crystallized by cooling. *Uses* include the production of other divalent mercury derivatives, as a nitrating agent in organic synthesis, and as an analytical reagent.

Mercury(I) sulfate [7783-36-0], Hg_2SO_4, M_r 497.24, ϱ 7.56 g/cm^3, is a colorless microcrystalline powder (monoclinic crystal system) that is very sensitive to light. The compound is prepared by precipitation from a solution of mercury(I) nitrate with sulfuric acid or sodium sulfate solution, or by electrochemical oxidation of mercury in dilute sulfuric acid. It is used as a depolarizer in standard cells after Clark and Weston.

Mercury(II) sulfate [7783-35-9], $HgSO_4$, M_r 296.65, ϱ 6.49 g/cm^3, is a white powder (rhombic crystal type). It is prepared by fuming mercury with concentrated sulfuric acid or by dissolving mercury(II) oxide in dilute sulfuric acid and evaporating the resulting solution until the compound crystallizes. Mercury(II) sulfate is used in analytical chemistry to bind chloride ions in the determination of the COD of wastewater [109] ; as a catalyst in the production of acetaldehyde from acetylene (⟶ Acetaldehyde – Production from Acetylene) and of anthraquinonesulfonic acids (⟶ Anthraquinone Dyes and Intermediates – Anthraquinonesulfonic Acids) ; and as a depolarizer in galvanic elements.

11.1.5. *Mercury – Nitrogen Compounds*

Reaction of mercury(II) compounds with ammonia solution leads, depending on reaction conditions, to amine complexes or mercury(II) nitrogen compounds. Of the numerous compounds known, only mercury(II) amidochloride has any practical importance.

Mercury(II) amidochloride [10124-48-8], $HgNH_2Cl$, M_r 252.07, ϱ 5.38 g/cm^3, is a fine, white crystalline powder with a rhombic crystal lattice. It is insoluble in water and in ethanol, and soluble in warm acid, ammonium carbonate solution, and sodium thiosulfate solution. On heating it decomposes without melting. The compound can be precipitated from mercury(II) chloride solution with an ammonia solution. Mercury(II) amidochloride is used in the treatment of severe skin disease, as an eye ointment, and as a veterinary preparation; its importance is declining because of the development of mercury-free products.

11.1.6. *Analysis, Storage, and Transportation; Protective Measures*

Analysis. Determination of the purity of mercury compounds, which consists of the determination of trace amounts of foreign cations and anions, involves specific reactions of these ions [110] ; conventional methods for the trace analysis of cations have been supplemented or replaced by methods involving the simultaneous determination of several elements by means of plasma emission spectroscopy [111].

Storage and Transportation. Plastic-lined steel drums are normally employed for packing. Small amounts (e.g., for chemical laboratories) are usually placed in plastic or glass bottles. Many compounds are light-sensitive and must, therefore, be adequately protected from light sources. Proper consideration must be given to the chemical and toxic properties (see Chap. Toxicology and Occupational Health) of mercury compounds and the necessary protective measures; this is particularly true in container labeling.

Protective Measures. Most mercury compounds, because of their toxicity (see Chap. Toxicology and Occupational Health), require the same protective measures during production and processing as metallic mercury. Furthermore, environmental protection necessitates appropriate precautions (see Chap. Environmental Protection).

11.2. Organic Compounds [112], [113]

Organic mercury derivatives are among the oldest known organometallic compounds. Organometallic compounds of *divalent mercury* are stable toward air, oxygen, and water. In contrast, organic derivatives of *monovalent mercury* are unstable and can be prepared only at low temperature. After 1990, use of organic mercury derivatives in the Federal Republic of Germany is difficult because mercury is not allowed in industrial effluent or wastewater.

Organomercury compounds can be divided into two major groups: compounds of the type R^1–Hg–R^2, where R^1 and R^2 are aliphatic or aromatic groups, and compounds of the type R–Hg–X, where R is aliphatic or aromatic and X is a halogen or an acid group.

11.2.1. *Production [114], [115]*

Synthesis of organic mercury compounds can be carried out by reaction of Grignard reagents (⟶ Magnesium Compounds – Organomagnesium Compounds) with mercury halides. To obtain pure products, the mercury salt and the Grignard reagent must contain the same anion

$$RMgX + HgX_2 \rightarrow RHgX + MgX_2$$

Furthermore, organic mercury compounds can be produced by the reaction of sulfinic acids or their sodium salts with mercury(II) halides [116]:

$$R-SO_2H + HgX_2 \rightarrow R-HgX + SO_2 + HX$$

Hydroxy- or alkoxymercury derivatives can be obtained via the solvomercuration reaction (Hofmann – Sand reaction) by addition of mercury(II) compounds to alkenes in aqueous, alkaline, or alcoholic solutions [114], [117]:

$$R^1-CH=CH-R^2 + Hg(OAc)_2 + R^3OH \rightarrow (R^3O)CHR^1-CHR^2HgOAc + AcOH$$

Organic mercury compounds can be converted to other organometallic derivatives by electrolysis or transmetallization [118].

11.2.2. *Compounds of the Type R^1–Hg–R^2*

Dialkyl- or Alkoxyalkylmercury Compounds. *Dimethylmercury* [593-74-8], CH_3–Hg–CH_3, M_r 230.60, a colorless, sweet-smelling liquid, is very toxic; it has a density of 3.069 g/cm^3, *bp* 96 °C, and is soluble in ethanol and diethyl ether. In acidic aqueous solution, dialkylmercury compounds are hydrolyzed to monoalkylmercury derivatives. Dimethylmercury is formed in organisms by enzymatic methylation of elementary mercury or a mercury compound. In an organism it is easily converted to methylmercury (CH_3–Hg^+) or methylmercury(II) chloride (CH_3–Hg–Cl). These species can react with free S–H groups of biologically important molecules, leading to the diseases that have been caused by mercury and its derivatives (Minamata, Niigata, Iraq; see Chap. Toxicology and Occupational Health).

Mixed dialkylmercury compounds (e.g., methylpropylmercury compounds) are less volatile than symmetrical dialkylmercury compounds (e.g., diethylmercury). Dialkylmercury derivatives are generally very reactive and can also undergo transalkylation with simple alkyl halides (e.g., ethyl iodide).

Diarylmercury Derivatives. The best known diarylmercury derivative is diphenylmercury, $(C_6H_5)_2Hg$, which is produced by direct mercuration.

11.2.3. *Compounds of the Type R–Hg–X*

Monoalkyl- and Monoarylmercury Carboxylates. The best known representatives of the monoalkyl- or monoarylmercury carboxylate series are phenylmercury(II) acetate and phenylmercury(II) oleate.

Phenylmercury(II) acetate [62-38-4], C_6H_5–Hg–O–$COCH_3$, M_r 336.75, forms colorless, lustrous crystals, *mp* 149 °C; it is soluble in ethanol, benzene, and acetic acid and sparingly soluble in water. This compound was used as a preservative for paints in an acetic acid –ethanol solution.

Phenylmercury(II) oleate [104-60-9], C_6H_5–Hg–O–CO–$C_{17}H_{33}$, M_r 559.17, is a white, crystalline powder, *mp* 45 °C; it is

insoluble in water and soluble in organic solvents or oils. It is used as a preservative against mold and as a catalyst in the production of adhesives and plastics.

Organic mercury salts play an important role as intermediates in catalyzed reactions, making these products of interest in carbene chemistry [114], [115], [119-121]. Addition of an ethereal solution of diazomethane to a solution of benzylmercury(II) iodide in tetrahydrofuran at 0 °C leads to immediate and quantitative formation of the carbenoid.

Monoalkyl- and Monarylmercury(II) Halides, Borates, and Nitrates. *Phenylmercury*(*II*) *chloride* [100-56-1], C_6H_5–Hg–Cl, M_r 313.18, and *basic phenylmercury*(*II*) *nitrate* [8003-05-2], C_6H_5–Hg–OH · C_6H_5–Hg–NO_3, M_r 634.45, are used as antimycotics and antiseptics.

The halides have higher melting points and are less irritating to the skin than other ionogenic salts. These organic mercury compounds were once used as antisyphilitics and diuretics. Their use for this purpose has been restricted or stopped because of their numerous side effects and toxicity.

Phenylmercury(*II*) *borate,* C_6H_5–Hg–O– $B(OH)_2$, M_r 338.50, is soluble in water, ethanol, and glycerol. It is used as a skin disinfectant and for the disinfection of medical instruments.

Monoalkyl- and Monoarylmercury Hydroxides. *Phenylmercury*(*II*) *hydroxide* [100-57-2], C_6H_5–Hg–OH, M_r 294.72, is a white, crystalline powder, *mp* 197 – 205 °C, which is soluble in glacial acetic acid and ethanol, and sparingly soluble in water. Phenylmercury(II) hydroxide is used as a starting material for numerous organic mercury compounds [121], [122]. Esters of the type C_6H_5–Hg–O–CO–R, produced from the hydroxide, are used as fungicides (seed protectants) and disinfectants. Regulations for cosmetics in the Federal Republic of Germany permit the use of this compound as a preservative in eye makeup and makeup remover, up to a concentration of 0.007 % (based on Hg).

11.2.4. *Analysis*

Organic mercury compounds may be analyzed in the following ways: they can be determined *qualitatively* (1) by digestion with concentrated sulfuric acid and 30 % hydrogen peroxide or (2) by digestion with 10 % sulfuric acid and subsequent addition of dithizone (diphenylthiocarbazone) in carbon tetrachloride solution. In the presence of mercury the green solution turns orange. Organic mercury compounds can be determined *quantitatively* by atomic absorption spectroscopy.

12. Economic Aspects

Matthias Simon

A detailed description of the development of production is given in the metal statistics of Metallgesellschaft AG, Frankfurt [123] (Table 12). Over the last ten years, production figures have changed only slightly. Because of reduced demand, many mines and smelting plants are no longer operating or have greatly cut back production. Intervention by the former Soviet Union has seriously depressed the price of mercury to dumping price levels, although this has been resisted by Spain and Algeria. The change in the price of mercury since 1979 is shown in Table 13 [123]. A survey of previous mercury prices is included in [124].

1986	187.500	6.13	232.785	7.56
1987	245.640	6.54	295.503	7.87
1988	297.17	7.77	335.52	8.76

The main producers of mercury extracted by mining are as follows [125] (figures refer to flasks):

Algeria	23 000
China	20 000
Finland	2 300
Former Yugoslavia	2 000
Mexico	10 000
Spain	42 000
Former Czechoslovakia	4 400
Turkey	6 000
Former Soviet Union	66 000
United States	14 000[*]

[*] The sole producer in the United States discontinued mining oprations from the middle of 1987 to February 1988. The production for 1988 is 14 000 flasks.

The Algerian mercury producer, Entreprise Nationale des Nonferreux et Substances Utiles (ENOF), quotes production prices of $ 300 per flask. Most of the Chinese production is exported to the United States. China claims to have the largest mercury resources in the world. Guizhou Province contains five mines, accounting for ca. 90 % of Chinese production. Italy, once a large mercury producer, now imports mercury from Algeria, the Netherlands, and former Yugoslavia. In Mexico, ca. 350 t of mercury (ca. 10 000 flasks) was extracted from mines in 1986, a large part of the production being exported to Brazil and Argentina. Spanish mercury production is ca. 40 000 fl. The main importers are the United States, Belgium, Luxemburg, and France. The former Soviet Union produces ca. 67 000 fl of mercury; in contrast to the high export level in 1986, almost the entire production is now reserved for domestic use. The capacity of production plants at the Anzob antimony – mercury complex in Tadzhikistan has been doubled. The major proportion of Yugoslav production of ca. 2000 fl of mercury is exported.

The development of prices and production figures will certainly be influenced substantially by acceptance of the metal mercury, and in large sectors no foreseeable substitute exists. The utilization of mercury in a highly industrialized country such as the Federal Republic of Germany is shown in Table 14 [126]. The purchase of mercury by individual sectors has decreased sharply since 1980. The main user of mercury is the electrical engineering industry, followed by the alkali chloride industry. The use of mercury in paints, pigments, and pesticides has fallen sharply.

Table 14. Breakdown of mercury use (in tonnes) in the Federal Republic of Germany according to sector [126]

13. Toxicology and Occupational Health

Stefan Halbach

13.1. Chemical Forms and Mechanism of Action

The unique physical properties of mercury, especially its high vapor pressure and therefore partial occurrence in the vapor phase at room temperature, have been referred to above. In addition to the ingestion of mercury compounds (mercurials), intoxications can thus occur by the inhalation of the vapor. Among the numerous organic compounds, the short-chain alkylmercury compounds, mainly methylmercury, are most important from the toxicological point of view because of their chemical stability. In contrast, phenyl Hg compounds are rapidly degraded to inorganic mercury compounds in mammalian tissues and therefore are similar to inorganic mercury regarding their toxic effects.

The interaction of mercury with biological ligands is based on the very high affinity of the mercury cation (Hg^{2+} or $R\text{-}Hg^{+}$) to sulfur [127-129]. If the binding occurs to sulfhydryl groups relevant for the structure of a protein or for the cellular function, each will be seriously disturbed. Since sulfhydryl groups are ubiquitous, the high affinity of mercurials leads to their potent but unspecific inhibition as seen with many enzymes [130]. Nevertheless, cases of poisoning are characterized by defined clinical manifestations from the target organs. It is assumed, therefore, that the selective toxicity of the different forms of mercury results from a selective distribution to the various compartments. Distribution and the permeation of biological barriers (cell membranes, blood-brain barrier) depend on lipophilicity which is high for Hg^0 and for alkyl mercurials but low for mercury(II) salts and for organic compounds with polar groups [131], [132]. A further modulator of toxicity is the air-liquid partition coefficient of Hg^0 which favors the accumulation of mercury vapor in plasma and whole blood [133]. All these factors acting together with various routes of uptake create a distinct etiology and symptomatology in intoxications with different Hg compounds.

13.2. Exposure

Occupational exposure to Hg vapor occurs in specific industries and professions such as chlor-alkali electrolysis (mercury cell process), production and recycling of fluorescent lamps and batteries, and in dentistry offices. Background exposure originates from the release of minute amounts of vaporous and inorganic mercury from dental amalgam (see Section Dental Amalgam Fillings). Exposure to organic mercury compounds may occur in the chemical industry, whereas background exposure results from intake with food, mainly as methylmercury from seafood. In summary, the intake of all forms of mercury amounts to 11 – 28 µg per day for the general population in the USA and Europe [134] but is largely dependent on dietary habits.

13.3. Metabolism

13.3.1. *Mercury Vapor and Inorganic Mercury*

Both chemical forms have in many respects a common metabolism, except for the routes of uptake.

Absorption. Approximately 80 % of inhaled *Hg vapor* is absorbed from the lungs into the bloodstream. The dissolved vapor is rapidly oxidized to Hg^{2+}, partly in the erythrocytes and partly after diffusion into other tissues. This oxidation is catalyzed by the enzyme catalase in presence of traces of hydrogen peroxide [135], [136]. For humans, the absorption of inorganic mercury from ingested food was estimated to range between 5 and 10 % of the dose [137]. The gastrointestinal absorption of mercury(I) is sufficient to cause serious illness (pink disease, see Pink Disease.). The absorption from ingested *liquid mercury metal* is probably below 0.01 % [138]. The cutaneous absorption can be substantial as shown in patients suffering from nephrotic syndrome after the use of ointments containing inorganic mercury [139].

Distribution. In human blood, the red cell: plasma ratio of mercury after exposure to Hg vapor is between 1 and 2. Studies on animals and humans showed that mercury has an affinity for epithelial cells and glands [140]. Based on animal data, 50 – 90 % of the body burden is located in the kidneys, where a large portion is bound to metallothionein, a low molecular mass, cysteine-rich protein [141]. Inorganic mercury penetrates the placental barrier as shown by the good correlation between concentrations in fetal and maternal blood of mothers with amalgam fillings [142].

Excretion. As demonstrated by short-term exposure of volunteers to Hg vapor, half of the mercury excretion is through the feces and much less through the urine. After long-term exposure, the urinary route (60 %) predominates over the fecal route (40 %) which reflects the renal accumulation [143]. A small portion of absorbed ionic mercury is exhaled as vapor after reduction in tissues [144]. Tracer studies on volunteers revealed a fecal excretion of 75 – 92 % of the dose after ingestion of inorganic mercury [145].

Toxicokinetics. After exposure to Hg vapor or to mercury(II), the elimination half-life for the whole body is 58 d which is close to that of 64 d for the dominating Hg pool in the kidneys [138]. Upon short exposure to Hg vapor, about 90 % of the mercury in blood is cleared with a half-life of 2 – 4 d, followed by a second phase with a half-life of 15 – 30 d [146], [147]. Tracer studies on volunteers showed a half-life of 19 d for elimination of most of the mercury in brain [143], [147], [148]. Autopsies on mercury miners many years after termination of exposure revealed high amounts in the pituitary, probably bound as biologically inactive mercury selenide [149], which means that the half-life in brain could be in the range of years [138].

13.3.2. *Organic Mercury Compounds*

Reliable data are available for monomethylmercury (CH_3HgCl; Me-Hg) only which, therefore, shall be described here.

Exposure and Absorption. Nonoccupational exposure to Me-Hg occurs almost exclusively through the diet, mainly fish, and remains without effect at background levels. Subacute intoxication may occur after ingestion of contaminated food. Prenatal exposure leading to neurotoxic effects has been found in the epidemics (see Prenatal Exposure.). More than 90% of the methylmercury in the diet is absorbed into the bloodstream [150]. Exposure to dimethylmercury appears to result in a very high absorption through lung and skin (see Effects on the Nervous System.).

Distribution. About 90 % of the absorbed Me-Hg in whole blood is bound to the red cells; further distribution to the organs is completed within four days [151]. It appears from studies on volunteers that the brain-blood concentration ratio is about 6 [152]. Major depositions in other organs are found in liver and kidney. Of particular interest is the binding in hair during hair formation which facilitates the retrospective assessment of the exposure (see Effects on the Nervous System.).

Conversion and Excretion. In the mammalian organism, Me-Hg is converted to inorganic Hg. Macrophages in the spleen are possibly involved in this breakdown [153]; enteral Me-Hg may be demethylated by the intestinal microflora [154]. Binding of Me-Hg and of Hg^{2+} to glutathione in the liver and subsequent secretion into the bile seems to be the essential step for fecal excretion [155]. Inorganic Hg, being poorly absorbed in the intestine, is mostly excreted, whereas unmetabolized Me-Hg can be reabsorbed to a great extent (enterohepatic circulation).

Toxicokinetics. Me-Hg is so mobile in the body that the excretion is the rate-limiting step for elimination. Therefore, the elimination rate is proportional to the actual body burden and can be described by a single biological half-life [150]. The Iraq epidemic as well as studies on volunteers have shown that the whole-body half-life is 70 d. Half-life in blood appears to be about 50 d. For practical purposes, the amount of Me-Hg in 1 L of blood can thus be assumed to equal 1 % of the body burden or the daily intake for a 70-kg person in steady state [134].

13.4. Toxic Effects

13.4.1. *Mercury Vapor and Inorganic Mercury*

Acute exposure to high doses occurs accidentally by incautious handling of the metal or by suicidal ingestion of mercury salts. On the whole, such incidents are less frequent than long-time exposure to intermediate doses of Hg vapor in the occupational environment (at or below the threshold limit value) or to low doses released from dental fillings of amalgam (see Section Dental Amalgam Fillings). According to its importance for humans, the focus of this section will be on chronic exposure at low levels.

13.4.1.1. *Acute Toxicity*

Severe affections of the respiratory system (chest pains, dyspnoea, cough, hemoptysis, impairment of pulmonary function, and evidence of interstitial pneumonitis) resulted from the acute exposure of workers to mercury vapor at estimated levels up to 44 mg/m^3 for 4 – 8 h [156]. Mercurial pneumonitis was also observed in an episode of unsafe manipulations with metallic mercury at home [157].

The symptoms of acute toxicity of $HgCl_2$ usually consist of severe gastrointestinal damage, cardiovascular collapse, and acute renal failure. Given in acute massive doses, inorganic and organic mercury will denature proteins, inactivate enzymes, and cause disruption of any tissue with which it comes into contact in sufficient concentrations. Gastrointestinal lesions, ranging from mild gastritis to severe ulceration of the mucosa, and renal lesions resulting in renal failure were found in cases of human poisoning following oral ingestion of mercuric chloride. The lethal doses ranged from 29 to at least 50 mg/kg body weight [158].

13.4.1.2. *Chronic Toxicity*

Upon long-term exposure to toxic levels of Hg vapor, the central and peripheral nervous system is the critical organ. Chronic exposure to mercury salts, particularly in the working environment, often involves exposure to a mixture of salt and vapor and mainly affects the kidney.

Effects on the Nervous System. In early stages, occupational exposure to inorganic mercury may induce unspecific symptoms such as irritability, excitability, shyness, and insomnia. With longer lasting exposure, a fine tremor develops, initially affecting the hands and later spreading to the facial muscles, causing violent muscular spasms in the most severe cases. Parallel to the tremor, mercurial erethism develops which is characterized by severe behavioral and personality changes, increased excitability, loss of memory, and insomnia, which may develop into depression. In milder cases, erethism and tremor subside slowly over a period of years after cessation of exposure. Peripheral nerves may also be affected; pathological changes in conduction velocity have been observed in mercury-vapor exposed workers [159], [160].

Renal Effects. The nephrotoxic effect of inorganic mercury consists of two types of renal injury. The first is a glomerular lesion caused by an autoimmune reaction induced by mercury and resulting in antibody formation against the glomerular membrane, deposition of immune complex, glomerular nephritis, proteinuria, and nephrotic syndrome. The immunotoxic response has been extensively investigated in the rat model and appears to be controlled genetically [161]. The second lesion affects the proximal tubules in parallel with the accumulation of mercury in the tubular cells. This damage results in a loss of tubular enzymes (gamma-glutamyl transferase, beta-galactosidase and beta-glucuronidase) [162]. Reabsorption is also decreased which leads to an elevated excretion of trace elements such as zinc and copper [163].

Dose-Response Relationships of Neurotoxic and Nephrotoxic Effects. An extensive study on workers in chlor-alkali plants revealed that the persons exposed to mercury vapor at or below a level of 100 µg/m^3 showed no significant neurotoxic signs or symptoms [164]; in addition, there was no evidence of poisoning at exposure concentrations below 10 µg/m^3. Studies on groups with high occupational exposure have pointed to the importance of urine Hg peaks in excess of 500 µg/L for the development of neurological signs and symptoms [165], [166]. Urine values above 100 µg/L have been associated with decreased performance in psychomotor ability tests [167]. Evidence for effects at urinary concentrations < 50 µg/L remains inconclusive [168-170].

Studies on chlor-alkali workers showed the onset of *renal effects* at urine concentrations between 30 and 50 µg/L, corresponding to an exposure of 0.3 mg Hg/m^3 air and to a blood Hg level of ≥ 30 µg/L [162], [171]. On the other hand, no signs for renal dysfunction were found in occupationally exposed persons with a mean urine Hg concentration of 56 µg/g creatinine [172].

Thus, early effects on the two target organs for inorganic mercury occur at similar Hg concentrations in air and urine. Preclinical neurological and renal effects may be detected with subtle diagnostic methods between 50 and 100 µg Hg/L urine, corresponding to more than 20 µg/L blood, whereas clinical manifestations can be expected to increase at levels above 200 µg/L urine. Hence, these concentrations can be viewed as the lowest observed effect level (LOEL).

Skin Reactions. Metallic mercury has rarely been found to cause hypersensitivity. However, mercury compounds (thiomersal and ammoniated mercury) give rise to a type IV cell-mediated delayed hypersensitivity reaction [173]. Few cases of allergic dermatitis have been reported among dental personnel. A very rare condition observed in individuals with dental amalgam fillings are lesions of the oral mucosa such as lichen planus [174].

Pink Disease. A particular syndrome occurring in children exposed to inorganic mercury is pink disease (acrodynia, Feer's disease). It is characterized by irritability, sleeping disturbances, copious sweating, photophobia, and generalized rash. The extremities become cold, painful, red, and swollen, and the skin desquamates. Calomel-containing teething powder and ointments as well as sources of Hg vapor in the children's environment are the cause of this disease of unknown etiology [175-177].

13.4.2. *Organic Mercury Compounds*

Phenyl-Hg compounds are rapidly metabolized to inorganic Hg [143] which makes their toxicity similar to that of inorganic Hg. Alkyl compounds are more persistent and produce specific signs of disease.

Effects on the Nervous System. The syndrome occurring upon subacute and chronic exposure to *methylmercury* was first described for a group of occupationally exposed workers [178]; it has reappeared in the epidemics in Minamata [179], [180] and Iraq [181]. The typical sequence of effects is paresthesia in the extremities, ataxia, dysarthria, constriction of the visual field, and deafness. The beginning of symptoms is preceded by a latent period from one to four months.

The mechanism for the selective damage of methylmercury to the nervous system is still unclear and is debated in various experimental approaches. Muscular weakness observed in severe cases of poisoning is possibly related to the inhibition of acetylcholine transmission at the neuromuscular junction [182]. Protein synthesis in nerve cells appears to be particularly sensitive to methylmercury [183-185]. Activated oxygen species and an increased lipid peroxidation may also significantly contribute to the alkylmercury-induced neurotoxicity [186].

Upon exposure to *dimethylmercury*, similar but more intensive symptoms develop after a longer latency period. The few cases of poisoning reported in the literature all ended fatally, which means that this compound should be considered as extremely toxic [187].

Dose-Response Relationships. The relationships between concentrations of Me-Hg in blood or hair and the magnitude or frequency of an effect had been studied in the epidemics (see Effects on the Nervous System.) as well as in populations with an unusually high consumption of fish. Among the last group, no signs of poisoning were found below blood Hg levels of 200 – 360 µg/L [150]. This is in accordance with the observations on adult Minamata and Iraq victims. The most sensitive groups of these developed paresthesia at blood Hg levels above 200 – 400 µg/L, corresponding to hair mercury levels of 50 – 125 µg/g [150]. Considering 300 µg/l as the lowest observed effect level in blood means that the daily uptake is about 300 µg for a person of this group in steady state (see Dose-Response Relationships of Neurotoxic and Nephrotoxic Effects.).

Prenatal Exposure. Estimates between 1.2 and 1.9 for the infant : mother blood-mercury concentration ratio reveal the

importance of the transplacental transfer of methylmercury [188]. Follow-up studies on the Iraq epidemic indicated that maternal hair levels of 10 – 20 µg/g raised the incidence of psychomotor retardation of the infant above the background frequency [189]. According to [134] this range of values in maternal hair must be considered as critical for the development of the fetal nervous system. Epidemiological studies on fish-eating populations of the Faeroe islands in the 1990s reported the possibility of slight neuropsychological effects in children of mothers with hair Hg levels of 4.3 µg/g during pregnancy [190], while a similar study in the Seychelles found no indication of such effects at 6 µg/g [191]. The mechanism underlying the prenatal neurotoxicity of Me-Hg may be a derangement of the migration of neurons to their proper location in the cortical layers at the time of the fetal brain development [192].

13.4.3. *Dental Amalgam Fillings*

A special case of exposure to inorganic mercury is dental amalgam for this is a long-term exposure to low levels on an epidemiological scale. Urine and blood Hg levels are clearly elevated in presence of amalgam if compared to amalgam-free persons, but remain within the normal range [193], [194]. These levels are influenced, however, by dietary organic Hg, rendering the estimation of the amalgam-related portion of blood Hg more difficult. A parameter more representative for amalgam-related mercury may be the Hg level in blood plasma which responds with high sensitivity to alterations of the amalgam status [195]. A toxicokinetic evaluation of the available data has shown that the daily Hg uptake from amalgam varies between 3 and 17 µg [196] which is in the same range as the dietary intake and within the limits of the acceptable daily intake ([197]; see Section Critical Levels, Risk Assessment). More recent estimations of the absorbed daily dose consistently revealed average levels below 10 µg/d [193], [198], [199].

13.4.4. *Carcinogenicity*

Me-Hg and, to a lesser extent, inorganic Hg have been shown to be potentially genotoxic in animal and in-vitro studies [134], [200]. However, the relevance for human exposure seems to be limited as clinical cases of cancer have not been linked to mercury so far.

13.5. Indicator Media and Reference Values

13.5.1. *Mercury Vapor and Inorganic Mercury*

Ongoing occupational exposure is equally well reflected by mercury levels in blood or urine (24-h urine or reference to creatinine) [168]. Low-level exposure to Hg vapor or inorganic Hg is easier to assess through total Hg concentrations in urine than in blood because methylmercury from food, which is poorly excreted by the kidney, does not interfere with the measurement. People without occupational exposure have Hg concentrations in blood of 3 – 5 µg/L and in urine up to 5 µg/L [143], [196], [201]. Under steady-state conditions in long-term exposure, the following proportionality can be assumed: a mercury concentration in air of 40 µg/m^3 equals about 15 – 20 µg/L blood and about 50 µg/L urine [138].

13.5.2. *Methylmercury*

It follows from the toxicokinetics that whole blood or red cells are the most reliable media for the assessment of body burden of Me-Hg. Urine is not satisfactory as it is a minor route of excretion (see Section Mercury Vapor and Inorganic Mercury). The concentration in scalp hair during its growth parallels closely that in blood and is about 250 times higher than in blood, hence hair Hg levels are useful in estimating actual and previous exposure [143]. The average concentration in background exposed populations is up to 5 µg/L in whole blood and 2 µg/g in hair [134].

13.6. Critical Levels, Risk Assessment

Factors applied to the LOELs (see Dose-Response Relationships of Neurotoxic and Nephrotoxic Effects.) scale them down to levels of acceptable health risks or to those assumed to have no effect if they are not exceeded (critical levels, regulatory levels). Depending by which institution they have been set, these levels differ to some extent, and therefore more than one are given where possible. In the workplace, the Hg concentration in air shall not exceed 100 [202] or 50 µg/m^3 [203], whereas for permanent inhalation, levels between 0.2 (minimum risk level) [204] and 1 µg/m^3 [205] are considered safe. For an adult, the provisional tolerable weekly intake of mercury with food shall not be more than 300 µg of total mercury, containing not more than 200 µg of methylmercury, which is about 1/10 of the LOEL [134], [197], [206]. The upper limit in drinking water is set at 1 µg/L (Germany) and is based on the analytical detection limit rather than on toxicological evidence.

Regular intake of small doses of methylmercury over extended time periods leads to steady-state concentrations in organs and biological fluids [150], which means proportionality between these concentrations. This is likely to hold also for the exposure to Hg vapor. Therefore, Hg determinations in blood, urine and scalp hair can be used as indicators of the mercury burden of target organs or of the whole body. Blood levels, indicating exposure to all forms of mercury, range normally below 5 µg/L with a critical value of 50 in occupationally exposed persons. Urine levels, being representative of exposure to inorganic and vaporous Hg, are normally below 10 µg/L with a critical limit of 100 in exposed workers [138], [202]. In cases of dietary overexposure, symptoms appear at hair levels of 50 – 125 µg/g (LOEL) [134]. Because of the neurotoxic susceptibility of the fetal brain the critical level in maternal hair during pregnancy is estimated at 10 µg/g [134].

1. Introduction and History

The use of metal complexes as dyes has its origins in *mordant dyeing*, a process that can be traced back to the Middle Ages. In mordant dyeing, textile dyes or the dyed fabrics themselves are treated with specific metal salts, which leads to both a bathochromic shift in color and a distinct dullness. Resistance to the effect of light or washing is also greatly improved. Metal compounds commonly employed earlier include aluminum, chromium, and iron salts.

Important events in the historical development of metal-complex dyes can be summarized as follows [5], [12]:

1887 Synthesis of the first metallizable azo dye, alizarin yellow, from diazotized 4-nitroaniline and salicylic acid (R. Nietzki)
1891 Formulation of the theory of coordination (A. Werner)
1893 Synthesis of the first metallizable 2,2′-dihydroxyazo dye (E. Bergmann and O. Borgmann)
1908 Elucidation of the stereochemistry of metal complexes (A. Werner)
1912 Synthesis of the first premetallized 1 : 1 chromium complex (R. Bohn, BASF)
1915 Patenting of a strong-acid dyeing process for 1 : 1 chromium complexes (Ciba)
1920 Marketing of 1 : 1 chromium complexes: the Neolan series (Ciba) and the Palatin Fast series (BASF)
1927 First synthesis of copper phthalocyanine (H. de Diesbach and E. von der Weid)

2. Structure of Metal-Complex Dyes

2.1. Chelates

Complexes or *coordination compounds* are systems in which a metal ion (the central atom) is chemically linked with one or more electron donors (ligands). A ligand with several donor groups capable of coordination leads to cyclic coordination compounds, which are designated as *internal complexes* or *chelates*. Such polydentate ligands greatly increase the stability of a complex relative to similar monofunctional

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a16_299

nucleophiles. The resulting increase in the tendency to form complexes, known as the *chelate effect*, was discovered by SCHWARZENBACH [14] and is discussed in [13, pp. 121 – 122].

The stability of metal chelates is described extensively in [9]. Generally speaking, stability is related to the formation of strain-free five- and six-membered rings, to the number of chelate rings per ligand, to the basicity of the ligands, and to the nature of the metal ion.

A characteristic feature of metal complexes is that the coordination number of the metal ion is greater than its valence. Typical coordination numbers observed in metal-complex dyes are 4 (most divalent ions) and 6 (in most trivalent metal ions). Chelation leads to changes in many physical and chemical properties, including absorption spectra, stability, charge, and solubility. These properties are exploited in dye chelates to modify color tones, the affinity of a dye for particular substrates, and colorfastness.

Figure 1. Types of chelate complexes
M = central metal atom; L = monofunctional ligand; X–X–X = chelate-forming ligand

Figure 1 illustrates the most important chelate types. Compounds in column A display a metal ion coordination number of 4, whereas those in columns B and C have the coordination number 6. Rows a, b, and c are assigned to bi-, tri-, and tetrafunctional ligands, respectively. Complex type Ac represents a tricyclic species capable of undergoing an additional ring closure to form a tetracyclic annulene. Metal ions with a coordination number of 4, such as copper(II), form 1 : 1 complexes with tridentate ligands, the fourth coordination site being occupied by another nucleophile (e.g., water, ammonia, or pyridine). Metal ions with a coordination number of 6, including chromium(III), combine with tridentate ligands to give 1 : 1 and 1 : 2 complexes (one metal ion joined to one or two dye molecules). In a 1 : 1 chromium complex, the three vacant coordination sites are usually occupied by water molecules because synthesis is performed in an aqueous medium.

Tridentate ligands are the most significant from the standpoint of applications. Metals having a coordination number of 4 usually give square planar complexes, whereas with a coordination number of 6 the ligands are arranged octahedrally around the central atom. Figure 2 shows the most important types of tridentate ligands from an industrial standpoint.

Figure 2. Tridentate ligands and their metal complexes
M = Cu^{2+}, Cr^{3+}, etc.

After metallization, dyes derived from 2,2′-dihydroxyazo (**1**), 2,2′-hydroxyaminoazo (**2**), and 2,2′-dihydroxyazomethine (**4**) ligands give the condensed five- and six-membered cyclic systems **1a**, **2a**, and **4a**, respectively, whereas 2,2′-hydroxycarboxyazo (**3**) and 2,2′-hydroxycarboxyazomethine (**5**) moieties lead to **3a** and **5a**, with two six-membered rings.

Figure 3. Geometric arrangements exhibited by octahedral complexes
A) Drew – Pfitzner structure, meridian arrangement with two tridentate ligands perpendicular to one another, one pair of enantiomers
B) Pfeiffer – Schetty structure, facial arrangement with two tridentate ligands parallel to one another, four pairs of enantiomers, one centrally symmetric isomer

Systems with larger numbers of ring atoms are extremely rare. One example described in the patent literature [15] is the 1 : 2 chromium complex of the dye formed by coupling 1-amino-2-phenylacetic acid with phenylmethylpyrazolone, resulting in one seven-membered and one six-membered ring. They are of no technical interest.

The "ligands" shown in Figure 2 are only fragments; they form part of benzene and naphthalene rings, pyrazolones, and open-chain keto – enol systems. The bonds joining metal atoms to nitrogen from the azo or azomethine groups are sometimes called "secondary valences", and may be characterized by arrows or dotted lines [13].

2.2. Stereochemistry and Isomerism

Three types of isomerism are associated with metal complexes bearing trifunctional ligands. The first arises from the fact that the ligands may occupy geometrically distinct positions around the central atom; the second is due to the possibility that either of the two nitrogen atoms in a given azo group can bind to the metal; finally, the complexing nitrogen in the hydrazone form of an azo dye is formally sp^3 hybridized, which produces two conformational possibilities.

The first type of isomerism is illustrated by octahedral 1 : 2 chromium and cobalt complexes, in which tridentate ligands may be arranged either perpendicular (Fig. 3 A) or parallel (Fig. 3 B) to each other. This results in eleven possible structural isomers. The meridial (*mer*) arrangement gives a pair of enantiomers [16], [17]. The resolution of these enantiomers into optically active forms was demonstrated by P. Pfeiffer and S. Saure [18]. Such "Drew – Pfitzner structures" are present in 2,2′-dihydroxyazo and azomethine dyes (5/6-membered rings). The perpendicular arrangement of the ligands has been verified by X-ray structural analysis [19].

The facial (*fac*) or sandwich orientation (Fig. 3 B) of 6/6-ring chelates is a consequence of steric factors [20]. Here, four enantiomeric pairs are possible, together with one centrally symmetric isomer. In the case of the 1 : 2 chromium complex of the azo dye derived from 1-(2-carboxyphenylazo)-2-naphthol, four isomers have been isolated by chromatography [21]. All four have the same molecular formula, but their spectra and solubilities differ. In solution, each of the isomers undergoes equilibration to regenerate the original mixture. Once again, the pro-

posed structure of one of these isomers has been confirmed by X-ray structural analysis [22].

With asymmetric 1 : 1 and 1 : 2 metal complexes a second type of isomerism becomes possible because different nitrogen atoms from the tricyclic ligands can be bound to the central atom in different ways. Two isomers may be distinguished in a 1 : 1 complex [23] and three in a 1 : 2 complex (Fig. 4) [24]. These isomers have been detected by NMR spectroscopy [25].

Figure 4. N-α,β-Isomers of 1 : 2 metal complexes $M = Co^{3+}$, Cr^{3+}

Such N-α,β-isomerism is precluded in complexes of the 1 : 1 and 1 : 2 types if the third position ortho to the azo function is occupied by methyl or methylene groups [26]. Thin layer chromatographic separation of N-α,β-isomers has been described [27].

The third type of isomerism is found in 1 : 2 complexes with 5/6-membered rings and is attributed to the tautomeric hydrazone structures of the azo ligands, in which an sp^3-hybridized nitrogen atom serves as the electron donor. Three conformationally distinct complexes arise [28]. A thorough study of this situation utilizing modern spectroscopic methods is reported in [29]. Figure 5 illustrates the tautomers containing only one 1-hydroxyl group, which can be used to synthesize cobalt complexes.

The fact that numerous isomeric complexes coexist in equilibrium means that the resulting colors tend to be rather dull. In contrast, planar dyes such as the copper phthalocyanines and copper formazans are brilliant in color.

Figure 5. Tautomerism in azo and azomethine compounds

3. Production

The chief synthetic methods for metal complexes are summarized in Table 1. Most 1 : 1 nickel and copper complexes are prepared from the corresponding salts at pH 4 – 7 in the presence of bases such as sodium acetate and ammonia between 25 and 70 °C. *Dealkylative coppering* is the method of choice for water-soluble polyazo compounds. This may involve initial formation of a 1 : 1 copper complex in which the ether group is already coordinated to copper. Reaction is carried out in the presence of buffers such as sodium acetate, alkanolamines, or pyridine at elevated temperature (> 80 °C). Nucleophilic substitution is facilitated by the neighboring azo group, and if X = H (Table 1), simultaneous oxidation is required (*oxidative coppering* [30]). Oxidative degradation of the original dye is a danger in this reaction, so very mild conditions are required. The 2,2′-dihydroxy copper complexes are formed from the corresponding 2-halogen compounds in strongly alkaline medium [31]. 2-Sulfonic acids are also susceptible to nucleophilic exchange.

Dealkylative and oxidative coppering represent technical processes, because few direct methods are known for preparing azo metal complexes with 2-hydroxy substituents on both sides of the azo group. This is a consequence of the limited availability of 2-aminophenols and the difficulty of coupling the corresponding diazonium salts (2-quinone diazides). Copper complexes prepared in this way can subsequently be converted to metal-free dyes and then to the corresponding chromium complexes [32].

Iron complexes are prepared under weakly acidic conditions at slightly elevated temperature (40 – 80 °C).

The 1 : 1 cobalt(III) complexes cannot be prepared in acidic solution. Nevertheless, the greater stability of cobalt(III) amine complexes [9], [33] can be exploited to obtain 1 : 1 cobalt complexes with three NH_3 ligands [34] or

the even more stable complexes with ethylenediamine, triethylenediamine, or phenanthroline [35]. Nitrite as a strong nucleophile also produces stable complexes [36].

The metal ion in 1 : 2 cobalt complexes is also trivalent, but such dyes are manufactured from the more stable cobalt(II) salts. Atmospheric oxygen serves as the oxidant, and reaction conditions are very mild: 40 – 80 °C and near-neutral pH. If cobaltization proceeds slowly, the metal-free dye may suffer degradation because it can act as an oxidant. The result is a decrease in yield, but important characteristics of the dye may also be adversely affected. The usual remedy is dropwise addition of dilute hydrogen peroxide along with the cobalt(II) chloride solution. Demethylative cobaltization requires temperatures > 100 °C, achieved by carrying out the reaction in high-boiling glycols. Base (e.g., ammonia, alkanolamines, or sodium hydroxide) must also be added.

The 1 : 1 chromium complexes containing sulfonic acid groups are prepared below pH 3 at 100 °C (disulfo derivatives) and up to 140 °C (monosulfonated compounds). A reaction temperature > 100 °C is achieved either in water under pressure or in glycols. The 1 : 1 chromium dyes are isolated from acidic solutions as their slightly soluble betaines (**7**) [5].

D = azo or azomethine residue

Irrespective of the number of sulfo groups, temperatures > 100 °C are always required in the demethylative incorporation of chromium. The usual source of chromium is chromium(III)

oxide (obtained as a byproduct of dichromate oxidation), which is first dissolved in hydrochloric, sulfuric, or formic acid.

Preparation of 1 : 2 chromium complexes generally requires higher reaction temperatures than the corresponding 1 : 2 cobalt compounds because the hexa-aquo chromium ion present in solution is very stable. This subject has been discussed in [9]. Chromium incorporation is usually conducted in near-neutral solution but can be accelerated by the addition of base. An anionic precomplex with tartaric, oxalic, or salicylic acid is used to prevent the precipitation of chromium hydroxide [37]. The 1 : 2 chromium complex with salicylic acid (**8**) is particularly effective.

8 [*68214-27-7*]

An alternative method of preparing 1 : 2 chromium complexes under milder aqueous conditions is based on the use of an alkaline dichromate – glucose solution, in which a very reactive chromium(III) accessory complex forms as an intermediate [38]. The process is most important in the synthesis of 1 : 2 chromium complexes containing sulfonamide groups. Special precautions are necessary because of the toxicological risk of handling solid dichromate.

The introduction of alcohols [39] and carboxamides [40] as solvents for azo dyes that are only slightly soluble in water represented a technical advance. Formamide is particularly important because it promotes formation of 1 : 2 chromium complexes by buffering the acid that is released. The slightly soluble complexes are isolated by dilution with water.

Introduction of chromium by demethylation requires the use of sodium dichromate in glycol, which serves as both a high-boiling solvent and a reductant.

Two routes are used for preparing 1 : 2 metal complexes: the addition method and mixed metallization. The addition method leads first to a 1 : 1 chromium complex (**7**), which is isolated and subsequently reacted with the metal-free dye **6** to give the symmetric 1 : 2 complex **9**. Use in the second step of a dye with a different structure (**10**) but still capable of forming complexes, provides a route to uniform asymmetric 1 : 2 complexes (**11**).

For economic reasons, large-scale synthesis of symmetric 1 : 2 complexes is usually carried

out without isolation of the intermediate, but synthesis of asymmetric 1 : 2 complexes (e.g., those with only a single sulfonic acid group) is necessarily a stepwise process.

Mixed metallization is particularly important in the synthesis of 1 : 2 cobalt complexes because of the inaccessibility of the corresponding 1 : 1 materials [41].

Two equivalents of an azo or azomethine dye are reacted with one equivalent each of a Cr(III) or a Co(II) salt to give a single symmetric 1 : 2 metal complex. If the reaction is conducted with two different dyes, both capable of forming complexes, a statistical mixture of 1 : 2 metal complexes arises, i.e., two symmetric complexes and one asymmetric complex:

All three of the resulting dyes can be detected chromatographically. The solubility of such a mixture is often higher than that of a mechani-

cally prepared mixture of the same dyes. Mixed metallization opens the way to a large number of potential combinations, permitting the manufacture of brown, olive, marine blue, and black color tones that are otherwise difficult to achieve.

Use of three diazo and three coupling components can result in up to nine metal-free azo dyes, and these in turn can lead to 45 different 1 : 2 metal complexes. If one begins with ten components the number of possibilities increases to more than 5000.

4. Ecology and Toxicology

Dyes may enter the environment at several points: during production, in the dye works, and during use of the finished goods [42]. Losses during production and use depend on molecular structure, but average values from the textile, leather, and paper industries appear to be about 10 % of the total annual production of 450 000 t [43].

The effectiveness of a dye is a function of its stability with respect to a wide range of chemical and physical influences. Thus, dyes are degraded only slightly during normal wastewater treatment due to short residence times and aerobic conditions. Nevertheless, between 40 and 80 % of the material is adsorbed onto the activated sludge. Further degradation in the sediment by reductive anaerobic processes is rapid.

Toxicity studies in fish, involving more than 3000 commercial dyes, revealed that seven metal complexes had an $LC_{50} \leq 1$ mg/L. Such concentrations are not present in colorless effluents leaving a wastewater treatment plant (dye concentrations ≥ 1 mg/L are clearly visible). Typical distribution coefficients P of the complexes in n-octanol – water allow their bioaccumulation in fish to be estimated. Values indicate that the dyes are not bioaccumulated because solubilities in water are either too high or too low [44]. Studies also indicate that toxicity to algae and inhibitory effects on clarified sludge bacteria are negligible [45]. Metal-complex dyes possess only slight acute toxicity [46]. A published list of dyes classified as toxic ($LD_{50} \leq 200$ mg/kg) does not include metal complexes; their LD_{50} values all exceed 2000 mg/kg. Proposals for the safer handling of dyes are described in [47]. Relevant international regulations are reviewed in [48].

Economic and technological factors, together with ecologically suspect dyeing practices (e.g., large amounts of heavy metals in mordant baths), preclude the use of natural dyes as an alternative to synthetic substances [49]. Heavy-metal residues (including chromium) in effluents from dye production pose a risk of water pollution, but they can be eliminated by precipitation with calcium salts [50]. Processes for removing residual heavy metals from the reaction mixture in the form of water-soluble complex dyes are described in [51].

Different problems are posed by the after chroming process in which a metal-free complexable dye is used to stain wool in a process similar to application of an acid leveling dye. The dye is then converted into a metal-complex dye directly on the fibers with the aid of sodium dichromate. Improved procedures have drastically reduced the concentration of chromium salts in the corresponding effluents [52]. A report on the cleaning of effluents from textile mills is presented in [53].

5. Uses of Metal-Complex Dyes

Metal-complex dyes are unsurpassed in terms of range of application. Apart from certain restrictions affecting a few synthetic fibers, virtually all substrates can be dyed or printed with these substances but with dull shades. No other class of dyes provides such a generally high level of fastness, particularly lightfastness. Countless shades from greenish yellow to uniform black can be obtained by using different metals and combining different metal-complex dyes.

5.1. Textile Dyeing

5.1.1. Wool and Polyamides (→ Azo Dyes, Chap. 3.2.1.4.→ Azo Dyes, Chap. 3.2.2.)

Worldwide wool production is about 1.6×10^6 t, with a very low growth rate. Wool constitutes only about 4 % of all textile fibers, but because deep shades such as blue, brown, and black dominate, the corresponding fraction of total

dye consumption is twice as great, namely 8 %. Technical and economic criteria for selecting wool dyes are discussed in [54].

Premetallized complex dyes constitute 30 % of all wool dyes, a proportion slightly less than that assigned to secondary chromium incorporation dyes [52]. These mordant dyes are still important, especially for dyeing wool in dark shades with very high fastness. Premetallized dyes are 1 : 1 chromium, 1 : 2 chromium, or 1 : 2 cobalt complexes (no other metals are used). Their anionic character is responsible for their great colorfastness with respect to the highly polar wool fibers, and it also has a decisive influence on the corresponding application technology.

On account of their pH stability, the 1 : 1-chromium complexes are synthesized at pH ≤ 3, 1 : 2 chromium and cobalt complexes are prepared at ca. pH 7. The same pH values are required for the dyeing of wool. On prolonged heating at 100 °C and pH > 9 the 1 : 1 chromium complex decomposes into the 1 : 2 complex and chromium hydroxide. At 100 °C and pH < 4, however, the 1 : 2 chromium complexes undergo disproportionation to form the 1 : 1 complex and the metal-free dye.

Although a multitude of shades can be found in wool dyed with metal complexes, only a few combinations of diazo and coupling components are widely used, and all the applicable dyes are based on chromium and cobalt because of fastness considerations and problems related to synthesis. The most important 1 : 1 and 1 : 2 chromium and 1 : 2 cobalt wool dyes are listed in Table 2.

The chief starting materials in the yellow, orange, and red ranges are anthranilic acids and 1-aminophenols, together with acetoacetic acid anilides and pyrazolones substituted by electron-withdrawing groups. More bathochromic colors are obtained with naphthols as the coupling component, including the important blue and black shades resulting from incorporation of diazotized 1-amino-2-naphthol-4-sulfonic acid and the analogous 6-nitro compound.

Major suppliers of wool dyes together with relevant trade names are summarized in Table 3.

The 1 : 1 chromium complexes containing sulfonic acid groups precipitate as betaines (**7**) during synthesis and must be converted with base into soluble salts (**12**) for dyeing purposes:

7 **12**

D = azo or azomethine residue

The coloristic and economic significance of 1 : 1 chromium complexes remains high even though they have been marketed since 1920. This can be attributed to high migration and high leveling capacity. Wetfastness in the light- and middle - color ranges is also excellent, remaining adequate even with deeper shades. However, the fact that strongly acidic conditions (pH 2) are required in the dyeing process is a disadvantage because wool is then subjected to hydrolytic damage. Use of more gentle conditions (i.e., pH 4) produces uneven dyeing due to compound formation between the chromium(III) ion and nucleophilic groups in the wool keratin, which in turn inhibits dye migration. This problem does not arise at pH 2 because of protonation [8]. Colorless bi- and trifunctional chelators can be used to displace H_2O ligands on 1 : 1 chromium complexes to give, without a significant shift in color tone, 1 : 2 chromium complexes suitable for gentle wool dyeing in weakly acidic baths. An example is the group of Neopalatin Fast dyes (**13**, BASF), with sulfosalicylic acid anilides as colorless ligands, which came on the market in 1954 [55]:

13

$n = 1, 2$
D = azo or azomethine residue

Other metal complexes suitable for dyeing wool are 8-hydroxyquinoline derivatives [56].

The 1 : 1 chromium complex modified in this way does not display any deficiencies from the standpoint of applications, but such dyes are not widely used for reasons of cost. An alternative gentle method proposed more recently for dyeing wool fibers involves 1 : 1 chromium com-

plexes in conjunction with anionic auxiliaries and alkali, ammonium, or silicofluorides (Neolan P dyes, Ciba-Geigy) [57].

The first nonsulfonated 1 : 2 chromium complex was marketed by Geigy in 1949. This dye, Irgalan Grey BL [*12218-94-9*] **14**, developed by G. SCHETTY, represented a milestone in complex chemistry [58]:

14

At about the same time, BASF was conducting research on the Vialone dyes. Unlike Irgalan Grey BL (which bears methylsulfone groups), these compounds require auxiliary water-solubilizing substituents. Vialone dyes were first marketed in 1951 [59] and are the least hydrophilic of the 1 : 2 metal complexes. For this reason they are used in dispersed form to dye nylon (e.g., C.I. Acid Yellow 59, 18 690, **15**):

15

The commercial success of the Irgalan dyes marked the beginning of intensive research worldwide, which in turn led to better understanding of the relationship between the chemical structure of 1 : 2 metal complexes and their color and fastness properties. By 1964, several product lines were available commercially, representing more than 800 individual products [12]. All were free of sulfonic and carboxylic acid groups; their water solubility was enhanced by incorporation of nonionic alkylsulfonyl [60], alkylsulfonylamino [61], cyclic sulfone [62], and especially sulfonamide groups, sometimes in the form of mono- or dialkylated derivatives [63]. Unlike 1 : 1 chromium complexes, these dyes can be applied to wool under neutral to weakly acidic conditions, so that the wool fibers remain largely intact. The resulting colors are even and key properties such as wet- and lightfastness are outstanding.

The mechanism of the associated dyeing process has been the subject of numerous investigations [64]. The 1 : 2 metal complex dyes containing a single sulfonic acid group possess two negative charges. They are readily soluble in water, are applied in weakly acidic dye baths, and provide even dyeings with good fastness. Most are prepared in stages; that is, the 1 : 1 metal complex with sulfonic acid groups is isolated first, and this is added in the presence of base to a tridentate azo or azomethine dye to produce a homogeneous, asymmetric 1 : 2 metal complex [65] (e.g., **16** [66]):

16

Proper selection of diazo and coupling components permits optimization not only of the color but also of such characteristics as leveling capacity and fiber affinity. Compared with 1 : 1 chromium complexes, monosulfonated 1 : 2 chromium and cobalt complexes result in more intense color and less damage to the wool; furthermore, they are generally easier to synthesize than unsulfonated complexes (reaction temperature $< 100\,°C$). Manufacturing processes have been described that avoid isolation of the intermediate 1 : 1 chromium complex [67].

The monosulfonated dyes marketed under the trade name Lanacron (Ciba) in 1960 were followed ten years later by a series of disulfonated metal-complex dyes (Acidol-M, BASF). These are the most hydrophilic of all metal-complex dyes, and possess three anionic charges (e.g., C.I. Acid Blue 193, 15 707 [*75214-58-3*], Acidol Dark Blue M-TR, **17**):

17

Dyes of this type have been known since 1932 [68] but were studied in detail only after 1956 [69]. The hydrophilic character of these dyes require the addition of suitable leveling agents for deep and even dyeing [70].

Economical, relatively brilliant colors with high lightfastness are obtained under weakly

acidic dyeing conditions. The wetfastness of these materials is superior to that of all other metal - complex dyes, which has enabled them to capture a relatively large market share within a very short time. Wetfastness can be increased further by the addition of polyquaternary ammonium compounds, particularly in the case of chlorinated (shrink-resistant) wool. The result is a machine-washable wool product [71].

The principal applications of wool-reactive dyes also occur in this context. Such dyes were first marketed in 1960 under the trade name Procilan (ICI). The reactive moiety is the acrylamide residue ($-NH-CO-CH{=}CH_2$) [72].

Compared with the corresponding chromium complexes, 1 : 2 cobalt complexes are generally distinguished by their much greater lightfastness, with color shades shifted in a hypsochromic sense.

Dyed synthetic polyamide materials undergo photochemical degradation when exposed to light and heat. This is particularly disturbing with such items as automobile seat covers. Stabilization can be achieved by the use of copper complexes [73], including complex **18** with a bisazomethine ligand:

18

Synthesis of a 1 : 1 Cobalt Complex Stabilized with Nitrite [36]: A mixture of 28 g of $CoSO_4 \cdot 7\,H_2O$ and 42 g of $NaNO_2$ is dissolved in 400 mL of water. The solution is cooled to 10 °C, and 51 g of the dye is then added and partially dissolved. The dye is obtained by acid coupling of diazotized 2-amino-4,6-dinitrophenol with 2-phenyl-aminonaphthalene-4′-sulfonic acid. To ensure complete dissolution, 50 g of dimethylformamide is then added dropwise, the pH being kept at 5.0 – 5.5 by addition of HCl. Metallization commences immediately and is complete within 2h. The 1 : 1 cobalt complex is precipitated by addition of NaCl, isolated by filtration, washed with water, and dried.

Demethylative Incorporation of Chromium to Give the 1 : 1 Chromium Complex 19 [74]**:**

19 [*80004-31-5*]

To obtain **19**, 400 mL of 17 % HCl is added to 376 g of 5-amino-2-chlorohydroquinone dimethyl ether in 2800 g of ice water. Diazotization is accomplished by addition of 620 mL of 23 % $NaNO_2$ solution at 0 – 5 °C. Excess nitrite is reacted with amidosulfonic acid. The filtered diazo solution is introduced into a solution of 450 g of 1-hydroxynaphthalene-5-sulfonic acid in 3200 mL of ice water containing 70 g of NaOH solution and 100 g of Na_2CO_3. Coupling is complete within 2 h. The pH is then adjusted to 1 with HCl. Next, a solution of 300 g of Cr_2O_3 in 300 g of formic acid and 2000 mL of water is added, and the mixture is heated in an autoclave at 130 °C for 3 h. After cooling, the product is separated by filtration and dried. A black powder is obtained (yield: 750 g). The product dyes wool and leather grayish blue.

Synthesis of the 1 : 1 Chromium Complex 20 with a Colorless Ligand [55]:

20

A mixture of 20 g of the 1 : 1 chromium-containing monoazo dye obtained from diazotized 3-amino-4-hydroxybenzenesulfonamide and 2-hydroxynaphthalene, 400 mL of ethanol, 14 g of crystallized sodium acetate, and 15 g of 2-hydroxy-5-sulfobenzoic acid phenylamide is boiled for 2 h with stirring. After cooling the

solution is evaporated. The residue is a water-soluble dye for producing bordeaux red shades in wool from weakly acidic baths.

Synthesis of the Symmetric 1 : 2 Chromazo Dye 21 [75]:

21

Diazotized 1-aminonaphthalene-4-sulfonic acid is coupled with 1-acetylamino-2-hydroxybenzene, after which the acetylamino group of the monoazo dye is saponified. The compound is then diazotized a second time and coupled with 2-naphthol. A 52-g portion of the resulting disazo dye is dissolved in 2000 mL of water containing 6 g of NaOH at 100 °C. To this solution is added dropwise, over the course of 30 min, 200 mL of an aqueous solution containing 8.1 g of $K_2Cr_2O_7$ and 13.5 g of glucose. Once chromium incorporation is complete, the mixture is cooled to 60 °C, mixed with 250 g of NaCl, and filtered. After drying, a brown-black powder is obtained which dyes wool in fast brown shades.

Stepwise Synthesis of the Asymmetric 1 : 2 Chromazo Dye 22 [74]**:**

22 [*80004-32-6*]

A mixture of 40 g of the azo dye obtained from 1-diazo-2-naphthol - 4 - sulfonic acid and 2-naphthol is heated with 40 g of the 1 : 1 chromium complex **19** in 500 mL of water at 80 °C and stirred with aqueous NaOH at pH 7.5 for 5 h. The mixture is then cooled and the product is salted out with NaCl. Drying leads to a black powder that dyes wool and leather reddish blue. The resulting colors are fast, particularly on shrink-resistant wool.

Synthesis of the Statistical 1 : 2 Chromazo Dye Mixture 23 [76]:

[30112-70-0]

[81161-61-7]

[53036-47-8]
23

A suspension of the azo dye obtained from 18.8 g of 2-aminophenol-4-sulfonamide and 17.4 g of 1-phenyl-3-methylpyrazolon-5-one is mixed with a suspension of the azo dye obtained from 29.5 g of 6-nitro-1-diazo-2-naphthol-4-sulfonic acid and 17.5 g of 2-naphthol, and the mixture is adjusted to pH 5.5 with glacial acetic acid. Then, 28 g of chromium(III) acetate is added and the mixture is refluxed for 4 h. Once chromium incorporation is complete the dye solution is filtered, cooled to room temperature, and treated with NaCl to precipitate the chromium mixed-complex dye, which is then filtered and dried. This dye imparts an intense dark brown color to wool and polyamide fibers; it also has good leveling and fastness properties.

Synthesis of the Asymmetric 1 : 2 Chromazo – Azomethine Dye 24 [77]:

24 [110305-03-8]

A 1 : 1 chromium complex is prepared from diazotized 2-amino-5-nitrophenol and 1-hydroxynaphthalene-4-sulfonic acid. Then, 38.9 g of this dye (which contains ca. 5.2 g of chromium) is suspended in 500 mL of water and mixed with 23.4 g of 2-amino-1-hydroxy-4-nitrobenzene-6-sulfonic acid and 26 g of the monoazo dye obtained from diazotized 1-amino-2 - chlorobenzene and salicylaldehyde. The reaction mixture is heated to 80 – 85 °C, adjusted to pH 7 with NaOH, and maintained at this temperature and pH until starting materials are no longer detectable. The product is then precipitated by addition of NaCl and separated by filtration. After drying, a dark powder is obtained which dissolves in water to give a green solution that imparts olive-green shades with good fastness on polyamides.

Synthesis of the Symmetric 1 : 2 Chromium Bisazomethine Dye 25 [78]:

25 [82269-28-1]

A mixture of 112.5 g of the azo compound obtained from diazotized 2-amino-1,4-dichlorobenzene-5-sulfonic acid and salicylaldehyde is stirred with 42 g of anthranilic acid in 1200 mL of water and heated to 50 °C for 1 h with 12 g of NaOH and 50 g of sodium acetate. A chromium(III) formate solution prepared from 12 g of Cr_2O_3, 14 mL of formic acid, and 250 mL of water is then added, and the mixture is heated under reflux until thin layer chromatography reveals complete conversion to the 1 : 2 chromium complex. The pH is then adjusted to 7.8 with NaOH, and the complex dye is isolated by filtration and evaporation or spray drying. The brown dye powder (246 g, 33 % of which consists of sodium salts of acetic and formic acids), gives light- and wetfast reddish yellow colors with wool and synthetic polyamides.

Synthesis of the Symmetric 1 : 2 Cobalt Bisazomethine Dye 26 [79]:

26 [*41043-60-1*]

A mixture of 44.9 g of 75.7 % 2-amino-6-nitrophenol-4-sulfonic acid and 18.5 g of salicylaldehyde is heated to boiling in 300 mL of 20 % sodium acetate solution. The suspension is then mixed at 60 °C with 19 g of $CoCl_2 \cdot 6\,H_2O$, and 17 mL of 30 % H_2O_2 solution is added within 15 min. This causes the suspension to pass almost entirely into solution. The product is precipitated with NaCl and KCl, filtered, and dried. It yields exceptionally lightfast colors with wool and polyamides.

Synthesis of the Asymmetric 1 : 2 Chromium Azomethine Complex Dye 27 [80]:

27 [*85140-75-6*]

2-Hydroxybenzaldehyde (12.2 g) is added dropwise with stirring to a solution of 11.0 g of 1-(*β*-aminoethyl)pyrrolidine and 12.0 mL of acetic acid in 100 mL of water. The mixture is stirred at 50 °C until the aldehyde has dissolved and a yellow solution of the azomethine is obtained. This mixture is further diluted with 100 mL of water at 70 °C, and 61 g of a 1 : 1 chromium complex is then added with stirring. This 1 : 1 complex is obtained as the coupling product of diazotized 1-amino-2-hydroxynaphthalene-4-sulfonic acid and 1-hydroxynaphthalene-8-sulfonic acid (C.I. Acid Blue 158). Stirring is maintained, and the pH is adjusted with dilute NaOH to 7.2 – 7.5 at 70 °C. About 13 g of NaOH is consumed before formation of the 1 : 2 complex is complete, a process that can be monitored by thin layer chromatography. The resulting complex is precipitated with 120 g of NaCl. The precipitate is filtered at room temperature and dried at 80 °C to give 82 g of a water-soluble dye that imparts a deep blue light- and wetfast color to wool and synthetic polyamide fibers.

5.1.2. Cotton

The application of copper-containing substantive (direct) dyes to cotton has long been known. One example of such a dye is Sirius Light Blue 3 RL [*13217-74-8*] (**28**), C.I. Direct Blue 93, 22 810 [81].

28

Dimeric copper-containing direct dyes based on 4,4′-diaminodiphenyl-3,3′-diglycolic acid

were marketed by I. G. Farbenindustrie as Benzo Fast dyes (e.g., Benzo Fast Red CGL, C.I. Direct Red 180). The incorporation of copper in complex-forming di- and polyazo direct dyes considerably improves their light- and wetfastness. The Indosol direct dyes introduced by Sandoz (mostly copper-containing direct dyes) show increased wetfastness [13, p. 135]. They are reactant-fixable dyes that are cross-linked on and with the fiber after dyeing in the presence of a special reactive agent.

The 1 : 2 metal complex dyes with low affinity for cellulose can be made to bind to cotton by introduction of an appropriate reactive group [72]. Thus, black print is obtained on cotton by employing reactive dye **29** [82]. The corresponding pure 1 : 2 chromium complex [*79828-44-7*] results in a cloudy blue color, whereas the pure 1 : 2 cobalt complex [*79817-89-3*] gives a glossy red.

29
M = Cr:Co ≈ 3:1

By incorporating specific substituents metal-complex dyes can be used to print and dye cotton – polyester blends in various shades [83]. Previous commercial lines include Dybln (Du Pont) and Cellestren (BASF), containing tetracyclic nickel complexes such as **30**.

Synthesis of the Metal-Complex Dye 30 for Cotton [83]:

30 [*103850-03-9*]

The coupling product of 2-nitroaniline with furfuryl-5-aminopyrazole (31 g) in 300 mL of dimethylformamide is treated with 12 g of anhydrous nickel acetate and 56 g of K_2CO_3, and the mixture is stirred for 2 h at 130 °C. The olive-green reaction product is precipitated at room temperature by addition of 250 mL of methanol. The precipitate is separated by vacuum filtration, washed with a little methanol and then with water, and dried at 70 °C under vacuum. The resulting powder is crushed to permit preparation of a finely divided aqueous dispersion. Application to polyesters and mixed polyester – cottons according to patent DE-PS 1 811 796 results in fast olive colors.

Special auxiliaries are required when printing or dyeing with such substances because they act as disperse dyes.

5.1.3. Polypropylene

Polypropylene is a very hydrophobic fiber. It is used mainly in carpets and cannot be dyed with anionic dyes because it does not have any relevant functional groups. Since a high degree of lightfastness is required, the material is polymerized in the presence of nickel salts. Subsequent treatment with dyes capable of complexation results in the formation of nickel complexes during the dyeing process.

Appropriate dyes include nitrogen heterocycles with azo groups α to the nitrogen atoms and a hydroxyl group ortho to the azo group. 2-Aminothiazoles and 2-aminobenzothiazoles [84], 2-aminopyridines, pyrazoles, and imidazoles are used as the diazo components. Alternatively, the heterocycle may be incorporated into the coupling component [85].

Synthesis of the Dye 31 for Dyeing Polypropylene [85]: 2-Amino-4-chlorophenol (14.4 g) is slurried with 25 mL of 10 % NaOH, dissolved by the addition of 150 mL of water, and treated with 70 mL of 10 % $NaNO_2$ solution. The filtered solution is added dropwise with stirring (over ca. 30 min) to a mixture of 30 mL of concentrated HCl and 150 g of ice. Diazotization occurs within 1 h at 0 – 5 °C, and excess nitrite is subsequently decomposed by the addition of amidosulfonic acid. A solution of 13.2 g of 1-methylimidazo[1,5–*a*]pyridine in 70 mL of

10 % HCl is then added dropwise to the diazotization mixture. The solution is brought to pH 4 – 5 by the addition of ca. 100 mL of saturated aqueous sodium acetate, and the resulting dye is separated by vacuum filtration, washed, and dried. The product consists of 21.7 g of material corresponding to formula **31**, which is pure by thin layer chromatographic standards. It is a brown powder that dyes nickel-modified polypropylene fibers a greenish blue.

31 [*83156-84-7*]

5.1.4. Dust-Free Preparations

Toxicological, ecological, and process technology considerations have led to a demand for dye preparations that do not produce dust. Such formulations greatly simplify handling on the part of the customer [86]. The problem can be approached in several ways, including the addition of high-boiling mineral oils, use of liquid preparations, or dye granulation. The latter two variants have been intensively studied by major dye manufacturers in recent years.

The chief requirements with respect to liquid preparations are a high storage stability, a high concentration, and good miscibility with water. These are met by adding water-soluble solvents such as polyglycols, poly(glycol ethers) [87], or cyclic lactams [88].

Synthesis of a Liquid Dye [88]: β-Naphthol (4320 g) is dissolved in a mixture of 6277 mL (5712 g) of 25 % ammonia, 7740 g of pyrrolidinone, and 35 000 g of water (pH 12). The solution is then cooled to about 15 °C. During the course of 2 h, 14 334 g of 61.8 % 1-diazo-6-nitro-2-naphthol-4-sulfonic acid is added. If necessary, ammonia is used to adjust the pH to 9.5, and the solution is heated to reflux within 20 min. A mixture of 2232 g of $Na_2Cr_2O_7 \cdot 2\,H_2O$, 1500 g of glucose, and 6000 mL of water is then added within 15 min, and refluxing is maintained for approximately 1 h. A clear, stable dye solution results (C.I. Acid Black 52, 15 711 [*5610-64-0*]).

An alternative synthesis involving preparation of liquid dyes by phase separation is described in [89]. Another route for the production of highly concentrated, stable liquid preparations entails exchanging the usual countercations for ions that impart better solubility. For example, sodium ions required during synthesis can be replaced by lithium or substituted hydroxyalkyl-ammonium species [90].

Finally, salts produced during synthesis that interfere with the preparation of high-concentration liquid formulations can be removed by membrane separation techniques [91].

Dye granulates are solid dye preparations, and in this case stability is not a problem. Granulates are much more soluble in cold water than dye powders that have been treated with dust-reducing agents because the latter tend to clump when mixed with water [92].

5.2. Nontextile Uses

5.2.1. Leather

Leather can be dyed in two ways: by drum dyeing, usually with a dye powder, or by spray dyeing with liquid dyes. The most important leather powder dyes containing metal complexes are

Derma, Dermalicht (Sandoz)
Sellaecht, Sellacron (Ciba-Geigy)
Luganil (BASF)
Inoderm (ICI)
Baygenal (Bayer)

Many of these dyes can also be used for dyeing wool, furs, and hair. The most important liquid dyes are

Eukesolar (BASF)
Levaderm (Bayer)
Irgaderm (Ciba-Geigy)

Leather is often treated with di- and polyazo dyes of the direct type. Nickel salts sometimes serve as the metal ion donor, but copper salts and, especially in the important brown range, iron salts are more common. The use of chromium and cobalt compounds is relatively rare. In the case of dual coupling, resorcinol [93], 3-aminophenol [94], and *m*-phenylenediamine [95] are the preferred coupling components. The diazo

components are selected so that the greatest possible color intensity is obtained with chromium-tanned leather or leather that has been retanned with vegetable or synthetic products.

Various 1 : 2 chromium and cobalt complexes have been introduced for the *trichromic dyeing* of leather. In the trichromic process, mixtures of three dyes with different colors (e.g., yellow, red, blue, or gray) are used. An important prerequisite is that the dyes penetrate evenly into the leather and have the same affinity for different types of leather. This ensures that no color difference exists between the leather surface and the interior, a major consideration if polishing is contemplated [96].

Procedure for Dyeing Leather [97]: Chromium-tanned calfskin (100 g) is washed in 300 mL of water for 10 min at 30 °C and 24 rpm. The wash water is then removed and replaced by a mixture of 400 mL of water at 30 °C, 1 g of sodium formate, and 1 g of $NaHCO_3$. After neutralization for 45 min, the leather is again washed with 300 mL of water at 30 °C. The neutralized leather is then dyed in 300 mL of water at 50 °C with a dye mixture consisting of 9.072 g of the yellow dye **32**, 0.123 g of the red dye **33**, and 0.21 g of the gray dye **34**.

1:2 Co complex
32 [*10343-56-3*]

1:2 Cr complex
33 [*83914-74-3*]

1:2 Cr complex
34 [*111308-46-4*]

After 30 min, 3 g of a lubricant based on sulfonated chloroparaffins is added to the dye bath, followed after another 30 min by 0.5 g of 85 % formic acid. After an additional 20 min, the leather is rinsed with cold water and processed as usual.

Polyazo 1 : 2 chromium complexes give leather colors that show high resistance to poly(vinyl chloride) migration, a particularly important characteristic for sports shoes [98]. The black dye **35** is an example of such a substance; the iron complex of **36** gives yellowish brown shades:

1:2 Cr complex
35 [*119654-54-5*]

36 [*88332-66-5*]

Double 1 : 2 metal complexes, with up to six negative charges, show especially good incorporation into leather and outstanding fastness [99], [100]. For example, **37** produces fast brown shades.

37 [*103761-82-6*]

5.2.2. Paper

Octahedral metal complexes are seldom used for coloring paper because of their low substantivity and associated heavy discoloration of effluent water. The 1 : 1 copper complexes predominate because they tend to be more lightfast than metal-free dyes. Such dyes are often prepared by demethylative or oxidative coppering [30]. Cationized 1 : 1 and 1 : 2 metal complexes have

been intensely studied by Sandoz. They provide an almost colorless effluent, and the resulting paper shows good lightfastness and does not "bleed" upon contact with milk, fruit juice, alcohol, or mineral water [101].

Synthesis of the 1 : 1 Copper Complex 38 by Demethylative Coppering [102]:

38 [*92341-30-5*]

The aminoazo dye obtained by the weak-acid coupling of diazotized 2-aminonaphthalene-4,8-disulfonic acid with 2-methoxy-5-methylaniline (45.1 g) is dissolved in 500 mL of water and mixed with as much NaOH as required to give a neutral solution. This solution is then treated with $NaNO_2$ (6.9 g) and allowed to flow into a mixture of 25 mL of 30 % HCl and 50 g of ice. More ice is added as required to keep the temperature below 5 °C. As soon as diazotization is complete, excess nitrous acid is destroyed with a little amidosulfonic acid. The resulting suspension of diazonium salt is introduced into a neutral solution of 31.5 g of 5-hydroxy-2-phenylaminonaphthalene-7-sulfonic acid in 60 mL of water. The pH is kept between 8 and 8.5 by simultaneous addition of 100 mL of 10 % Na_2CO_3 solution. The coupling mixture is heated to 90 °C, mixed with 50 g of diethanolamine and a solution of 25 g of $CuSO_4$ (crystalline), 45 mL of 25 % aqueous ammonia, and 60 mL of water. It is then stirred for 8 h at 90 °C. The copper-complex dye obtained is precipitated with NaCl and separated by filtration. Paper treated with this dye acquires a pure blue color (maximum absorption at 595 nm) with particularly good light- and wetfastness.

Synthesis of the Bis 1 : 1 Copper Complex 39 by Oxidative Coppering [103]:

X = CH_3CONH–

39 [*119103-25-2*] (Cu-free)

The coupling dye obtained from diazotized 4,4′-diamino-stilbene-2,2′-disulfonic acid and 6-acetylamino-1-hydroxynaphthalene-4,5-disulfonic acid (88.5 g) is dissolved in 2000 mL of water at 60 °C. The solution is adjusted to pH 6 with a little glacial acetic acid, after which a solution of 25 g of $CuSO_4 \cdot 5\,H_2O$ in 75 mL of water is added. Then, 200 mL of 3 % H_2O_2 solution is added dropwise, the pH being maintained at 5 – 6 by addition of aqueous NaOH. After completion of oxidative coppering the mixture is heated to 80 °C and mixed with 450 g of NaCl. The precipitated dye is then isolated and dried. It produces blue shades in paper and cotton.

Synthesis of the Cationic 1 : 1 Copper Complex 40 by Demethylation [104]:

2 Cl^-

40

X = $(CH_3)_3\overset{+}{N}CH_2CONH$–

Dianisidine base (24.4 g) is coupled in the usual way with 65 g of the pyrazolone derivative **40** by using an aqueous medium acidified with HCl to pH 4. A red dye is obtained. A portion of this dye (34.4 g) is dissolved or suspended in a mixture of 400 mL of dimethylformamide, 42 mL of diethanolamine, and 13.3 g of copper acetate, and the reaction mixture is stirred for 4 h at 90 °C. The volume is then reduced by half with a rotary evaporator, and the red coppered dye is precipitated by the addition of 3000 mL of acetone.

5.2.3. Dyes for Anodized Aluminum

The 1 : 2 chromium and cobalt complexes of water-soluble azo dyes are suitable for coloring anodized aluminum [105]. For example, the symmetric 1 : 2 cobalt complex **41** imparts a black color to this substrate [106].

41 [*112144-04-4*]

5.2.4. Solvent and Ink-Jet Dyes

Solvent dyes are substances that are sparingly soluble in water but readily soluble in organic solvents such as alcohols, esters, and ketones. They have many applications, including foil printing and thread dyeing. Solvent dyes are also found in transparent lacquers, wood stains, and numerous office products (e.g., colors in felt-tip pen, ballpoint pastes, and ink for overhead projection transparencies). A few commercial product lines follow:

Orasol	(Ciba-Geigy)
Neozapon	(BASF)
Zapon	(BASF)
Savinyl	(Sandoz)
Lampronol	(ICI)
Valifast	(Orient Chemicals)
Aizen Spilon	(Hodogaya)

Anionic 1 : 2 chromium and cobalt complexes are particularly lightfast. To increase their solubility they are sometimes laked with organic bases such as long-chain aliphatic amines, guanidines, or cationic dyes. Laking converts the sodium salts produced during synthesis into salts containing organic cations [107]. Due to their insolubility in water, solvent dyes can be completely freed from salt by washing with water. They are marketed as 100 % dyes without additives. Solubilities up to 1000 g/L can be achieved in organic solvents, as in the case of the red dye **42** [108].

42

One new use of metal-complex dyes is ink-jet printing. In the ink-jet process, ink droplets are transferred to the substrate by spraying (→ Imaging Technology, Chap. 2.1.3.) [109]. The dye solutions are normally based on water, glycols, or cyclic aliphatic amides. The most important requirement is a total absence of salt because, otherwise, the capillaries of expensive print heads might become blocked or degraded by corrosion. The dye must not crystallize. Additional requirements for ink-jet colors are discussed in [110].

To obtain the desired properties, standard chromophores are replaced by residues such as **43** [109], **44** a formazan dye [111], or **45** [112] (see top of the next page).

Other examples include the laked (statistical) 1 : 2 chromium complex **46** used in printing inks (absorption maximum 580 nm) [113] and the 1 : 2 copper complex **47**, a lithium salt used as an ink-jet dye [114].

45 [*116932-38-8*]

47 [*113989-79-0*]

5.2.5. Pigments (→ Pigments, Organic)

Azo and Azomethine Pigments. Metal-complex dyes for use as pigments contain bi-, tri-, and tetracyclic planar systems and are devoid of solubilizing groups. Complexes of azomethine dyes play a much greater role than azo pigments with complex-bound metals. Nevertheless, a few azo dyes with astonishingly low molecular mass display pigmenting properties as well. For example, the bicyclic 1 : 1 nickel complex **48** [115] is suitable for mass dyeing polyolefin, polyamide, or polyester fibers. Numerous additional pigment applications are described in [115].

48 [*106335-41-5*]

Examples of yellow metal-complex pigments include 1 : 1 nickel compounds containing sym-

metric [116] or unsymmetric [117] heterocyclic azo moieties (e.g., **49**).

49 [*88717-24-2*]

Such systems are prepared from diazobarbituric acids (in turn obtained from benzenesulfonic acid azide by diazo group transfer) through coupling with 2,6-dihydroxypyridine-4-carboxamide followed by metallization with nickel chloride.

Reaction of salicylaldehyde with 2-amino-4-phenylphenol followed by treatment with copper acetate yields the bicyclic 1 : 1 copper azomethine dye **50** [118], obtained as a greenish yellow pigment.

50 [*21405-81-2*]

2-Hydroxyazo compounds form neutral bicyclic 1 : 2 complexes with divalent metal ions. The yellow pigment **51** [119] is particularly useful for coloring paint.

51 [*51931-46-5*]

Useful yellow pigments are also obtained upon condensation of iminoketoisoindolenine with 2-cyanomethylquinazolone. The yellow 1 : 2 nickel complex **52** [120] can be rolled into poly(vinyl chloride) films to give a yellow color with good fastness to light and migration. A paint pigmented with the nickel complex also exhibits very good resistance to light and weather.

52 [*106646-72-4*]

Synthesis of the Bicyclic 1 : 2 Nickel Pigment 52 [120]. The condensation product (32 g) of 2-cyanomethylquinazolone and iminoketoisoindolenine is stirred with 26 g of $Ni(COOCH_3)_2 \cdot 4\,H_2O$ in 300 mL of dimethylformamide for 16 h at 150 °C. The precipitate is then removed by hot vacuum filtration and washed with methanol and water. The product is a greenish yellow powder (yield 26 g).

Bicyclic yellow to red pigments are obtained by nitrosation of *N*-arylacetoacetamides, followed by reaction with ammonia (**53**) [121] or hydroxylamine (**54**) [122] and subsequent treatment with divalent metal ions. The products are actually tetracyclic due to the formation of additional rings by hydrogen bonding.

53 [*107861-02-9*]

54 [*91602-80-1*]

The same applies to the nickel diacetyldioxime dyes that have long been utilized in analytical chemistry (see Section 5.2.7). The structures of the corresponding platinum and palladium complexes have been studied and calculated [123].

Yellow pigments are derived from the oximes of arylazosalicylaldehydes by coupling with nickel salts (**55**) [124]; many applications are described in [124, pp. 13, 16 – 18].

55 [*106223-22-7*]

In the case of tricyclic pigments, azomethines are the compounds of greatest industrial significance; an example is the bisazomethine compound (**56**) [125].

56 [*64696-98-6*]

Yellow and orange 1 : 2 nickel complexes arise from formylated quinazolo[3.2.1]quinolones and *o*-phenylenediamines (**57**) [126].

57 [*97253-30-0*]

Synthesis of the Tricyclic 1 : 2 Nickel Complex 57 [127]. 4-Formyl-3-methyl-1-phenyl-5-pyrazolone (34.38 g) is stirred with 51.51 g of 1-(cyanophenylcarbamoylmethylene)-3-hydrazonoisoindoline, prepared from 1-(cyanophenylcarbamoylmethylene)-3-iminoisoindoline and hydrazine hydrate, in 1000 mL of ethyl cellosolve at 110 – 115 °C for 3 h. The resulting brown suspension is cooled to 90 °C and filtered. The product is washed with ethyl cellosolve and ethanol, and dried overnight at 80 °C under vacuum. The yield is 57 g (i.e., 69 % of theoretical) of the ligand in the form of a brown powder. Reactions of 46.8 g of the above ligand with 26.3 g of nickel acetate tetrahydrate in 800 mL of dimethylformamide for 4 h at 120 – 125 °C gives 20.3 g (39 % of theoretical) of an orange-red nickel complex.

Pigments obtained from aminoiminoisoindolenines treated with CH-active compounds and substituted hydrazones have been the subject of extensive research. Thus, the 1 : 2 nickel complex **58** is used for scarlet-red shades with outstanding fastness in both plastics and paints [127].

58 [*77135-16-1*]

Alternatives to the formylpyrazolone moiety in **58** include 3-acetyl-2,4-dioxyquinoline [128], 3-acetyl-4-hydroxy-6-methyl-2-pyridone [129], *N*-methyl-5-cyano-2-hydroxy-4-methyl-6-pyridone-3-aldehyde [130], and 1-formyl-2-hydroxy-3-naphthalenecarboxylanilide [131].

Phthalocyanine Pigments. See also → Phthalocyanines. The pigments produced in largest quantity are the copper phthalocyanines (tetraaza[18]annulenes). Because of their cyclically conjugated 18 π-electron systems, these tetracyclic compounds (e.g., **59**) are especially stable.

Phthalocyanine – metal complexes are synthetic aza analogues of the natural porphyrin

59

dyes hemin and chlorophyll (→ Phthalocyanines). Phthalocyanine is a tetrafunctional ligand that forms neutral complexes with divalent metal ions. Its copper complexes are impor-

tant as highly lightfast blue pigments; related halogen derivatives make excellent green pigments. Metal complexes of phthalocyanine are prepared directly from four identical subunits (e.g., phthalodinitrile) in the presence of the corresponding metal ions. The process occurs according to a "template reaction", in which four ligand molecules are coordinated to the metal ion in a spatial arrangement conductive to cyclization. Reaction of 2-aminobenzaldehyde with oxalyl chloride, followed by condensation with *o*-phenylenediamine, also produces tetracyclic pigments through a template reaction with divalent metals [132].

M = Ni [*59459-98-2*] (purple)
Cu [*76683-16-4*] (brilliant red)

5.2.6. Redox Catalysts

Metal-complex dyes used as redox catalysts are, like the pigments, polycyclic compounds. The well-known cobalt complex " salcomin" (**60**) binds reversibly with oxygen, thus serving, like the corresponding iron complex, as a model for biological redox catalysis.

60 [*14167-18-1*]

The catalysts are prepared from salicylaldehydes and aliphatic or aromatic diamines. Tetracyclic tetraaza[14]annulenes are used commercially as redox catalysts in the production of triarylmethane dyes. For example, the iron complex **61** can be synthesized from malonic dialdehyde and *o*-phenylenediamine [133].

61 [*50792-65-9*]

Aza[14]annulenes can also be prepared via tricyclic 1 : 1 metal complexes, which then undergo ring closure [134]:

The resulting tetracyclic complex precipitates as dark red crystals. It can be used to catalyze redox processes with atmospheric oxygen, as an electrocatalyst, or as the catalyst in electrochemical sensors for the determination of oxygen and nitrogen. The 1 : 2 cobalt complex of 1-[2-hydroxynaphthyl]azo-2-hydroxybenzene-5-sulfonic acid acts as a catalyst in the hydrogen peroxide oxidation of leucocrystal violet to crystal violet lactone, an important color-forming agent in carbon-free copy paper [135].

5.2.7. Analysis

Colored chelating agents have many applications in analysis. For example, complex-forming

dyes serve as analytical reagents for the gravimetric determination of metal ions (e.g., nickel diacetyldioxime). Chelators such as Eriochrome Black T or dithizone are useful indicators in complexometric titrations [136]. The coupling compounds prepared from 3,5-halogen-substituted 2-aminopyridines and 1,3-dialkylaminobenzoic acids give specific color reactions with vanadium, iron, cobalt, nickel, copper, and palladium ions. The resulting purple to blue chelates are sparingly soluble in water, but readily soluble in organic solvents, and have high molar extinction coefficients [137].

5.2.8. Photo Dyes

Color photography makes use of two types of metal-complex dyes: 1 : 1 chromium complexes bearing colorless ligands and 1 : 2 chromium complexes that are both characterized by the presence of a developer group such as the hydroquinone residue [138]. An example is dye **62** [139]:

62 [*79230-32-3*]

Numerous patents describe the photographic applications of nickel complexes of 2-amino-6-arylazo-3-pyridinol dyes [140].

5.2.9. Charge Stabilizers

Metal-complex dyes are rapidly gaining importance in the electronics industry, especially in photocopying. The basis of photocopying and requirements for the corresponding dyes are described in detail in [141]; see also → Imaging Technology, Chap. 2.1.1.

Toner for photocopying is prepared by molten extrusion of a resin with both a pigment (often carbon) and a charge stabilizer (charge control agent), followed by grinding to a particle size of 5 – 15 µm. The toner is then mixed with a carrier composed of fine iron particles to provide an electrophotographic developer.

Charge stabilizers (charge control agents) are negatively [142] or positively [143] charged 1 : 2 metal-complex dyes containing chromium, cobalt, or iron. Dye **63** [144] is a negative charge control agent, whereas dye **64** [145] is a positive charge control agent:

63

64 [*100012-90-6*]

Bicyclic 1 : 2 chromium salicylate complexes such as **65** are nearly colorless charge control agents [146].

65 [*119604-58-9*]

5.2.10. Optical Applications

Binary nickel, palladium, and platinum complexes of dithiol compounds show intense absorption between about 750 and 950 nm. They are used as IR dyes for optical drawing media or laser components, and also as IR absorbers for sunglasses and tinted windshields. In addition, such compounds are used as antioxidants for polymers and other organic materials, as corrosion inhibitors, and as protective layers for color photographic films or textile colors [147]. They are produced by reacting α-hydroxyketones with phosphorus pentasulfide, followed by introduction of the appropriate metal salts:

Bicyclic dithiolene complexes can be either neutral (**66**) [148] or anionic (**67**) [149]:

66 [*118422-25-6*]

67 [*105892-91-9*]

Bicyclic copper or nickel complexes of indoanilines (**68**) [150] are also suitable for optical drawing media.

68 [*111792-88-2*]
X = $-N(C_2H_5)_2$

Certain bicyclic (**69**) [151] and tetracyclic (**70**) [152] metal complexes exhibit discotic mesophases

69 [*78452-82-1*]

and are thus attractive as liquid crystals for electro-optical and thermo-optical display elements.

70 [*105358-51-8*]

Synthesis of 69 [151]. A solution of 160 mg of $CuCl_2$ in 3 mL of ethanol is added dropwise to a solution of 300 mg of bis(4-decylbenzoyl)methane in 1.5 mL of tetrahydrofuran at 40 °C. The mixture is stirred at 40 °C for 0.5 h, slowly mixed with 1 mL of 20 % ammonia solution, and stirred for 2 h. The resulting precipitate is separated by filtration and recrystallized from isopropanol to yield 250 mg of greenish bronze crystals. These are transformed into liquid crystals at 87 °C and pass into the isotropic fluid state at 130 °C.

6. Formazan Dyes

Formazan dyes are derived from the following basic structure:

(N^1 meso N^2)

The position of the substituents is given according to IUPAC nomenclature using the prefixes 1-, 3-, and 5-; the prefixes N^1, meso, and N^2 are

sometimes used. Formazans unsubstituted in the 1- and 5-positions and 1,5-dialkyl-substituted formazans are unknown. Aryl or heteroaryl groups are the most common 1,5-substituents. The 3- or meso position can be occupied by a variety of substituents (e.g., aryl, heteroaryl, H, OH, S-alkyl, halogen, NO_2, CN, and alkyl).

The 1,5-diphenyl and 1,3,5-triphenyl derivatives were discovered almost simultaneously by H. v. PECHMANN [153] and E. BAMBERGER [154] in 1892. Interest in these compounds was renewed in 1939 when G. LAKON [155] and R. KUHN and D. JERCHEL [156] found that colorless tetrazolium salts were very sensitive to biological reduction processes and were converted to deeply colored formazans:

In 1941 L. HUNTER and L. B. ROBERTS produced metal complexes from formazan compounds [157]. R. WITZINGER and coworkers introduced other complex-forming groups into formazans [158] which ultimately led to the discovery that metallized formazans could be used for textile dying. These chromophores have become important reactive dyes for cotton. Formazan dyes are also used in analytical chemistry because of the high color intensity of many of the metal complexes. The chemistry of formazans was first exploited in 1962 by MACDONALD to produce color photographs [159]. Early reviews of formazans and their coordination compounds can be found in [160–166].

6.1. Physical Properties and Structure

6.1.1. Metal-Free Formazans

With different aryl substituents (Ar, Ar′) at the 1- and 5-positions, the tautomers **71** and **72** are imaginable but have not yet been detected:

71

72

Each of these tautomers has four possible stereoisomers **73–76**:

syn-trans
73

syn-cis
74

anti-trans
75

anti-cis
76

Irradiation with visible light leads to rearrangement of many formazans from the stable red syn-trans form **73** into the yellow anti forms **75** and **76**. The anti forms exist only in solution; in the dark they revert to the closed syn-trans form **73** [167].

No stable isomers of triphenylformazan [*49624-20-6*] have been found. The compound has no vibrational bands in the IR spectrum between 2500 and 3200 cm^{-1} [168] and does not form salts in an alkaline medium. Its structure can be described as a quasi-aromatic chelate or as a resonance hybrid with the limiting structures **77** and **78** [167].

Alkyl substitution at the 3-position weakens the intramolecular hydrogen bond, hence 3-methyl-1,5-diphenylformazan exists in the open, syn-trans configuration **79** [169]:

77 **78**

79

This is recognized by the NH-vibrational band at 3360 cm^{-1} and the ease of salt formation in aqueous alkaline solution.

H. ZIEGLER investigated the influence of structure on the absorption maximum. He discovered that a bathochromic shift occurred when (1) electron-donating substituents were introduced at the 1-, 3-, and 5-positions, (2) on reaction with strong bases, and (3) above all on formation of chelates with metal ions. He attributed this effect to the formation of an alternately polarized six-membered ring,

whereby reduction of polarization leads to a hypsochromic shift and an increase to a bathochromic shift [170].

Polarization can also be modified by means of heat. Positive thermochromism is observed with benzothiazolylformazans (**80**): in cold ethanolic solution they are red and at 60 °C violet – blue [171]. The UV – visible spectrum of the blue form corresponds to that of the sodium salt

and is therefore assumed to have the anionic structure **81** [172].

In contrast, benzimidazolylformazans **82** exhibit negative thermochromism in oxygen-free solvents. On cooling to $-10\,°C$ in chloroform, for example, the color of the formazan with $R = CH_3$ and $R^1 = C_2H_5$ changes from violet ($\lambda_{max} = 545$ nm) to blue ($\lambda_{max} = 650$ nm). Deepening of color on cooling is due to hydrogen bond formation [173]:

6.1.2. Metal-Containing Formazans

Bidentate Formazans. The most outstanding property of formazans is their ability to form coordination compounds with metals. They behave as monovalent, bidentate ligands and form neutral 1 : 2 metal chelates with divalent metals:

Opinions about the geometry of these compounds vary. A planar structure has been proposed on account of their magnetic properties [174]. However, with 1 : 2 Ni(II) complexes their partial resolution into mirror-image isomers with (+)-quartz and their diamagnetism suggest a highly nonplanar structure [175].

Reaction with Cu(II) salts can produce various compounds depending on the reaction conditions: 1 : 2 Cu(II) chelates [157], Cu(I) complexes with 1 : 1 [176] and 1 : 2 stoichiometry [177], and the corresponding tetrazolium salts. The very low magnetic moment (1.4 BM, Bohr magneton) for the Cu(II) complex produced from triphenylformazan [157] suggests that it is a mixture of **83** (1.8 BM) and **84**, which does not have a magnetic moment.

83 [*53708-91-1*]

84

Tridentate Formazans. Formazans substituted with OH or COOH in the 2-position of the N_1- or N_5-aryl group have the same complexing properties as 2-hydroxy- (or carboxy)-2′-amino diaryl azo dyes. Similarly they also form 1 : 1 complexes with four-coordinate metals and 1 : 2 complexes with six-coordinate metals. As an amino system these formazans react more readily with cobalt salts than with chromium salts. The mostly blue cobalt(III) 1 : 2 complexes of type **85** [178] and the mostly gray-blue complexes of type **86** [179] are known:

85

86

Rings A and B may contain other substituents.

As with the tridentate azo compounds, ligands coordinated in 6/6-rings of type **85** are arranged facially and those coordinated in 5/6-rings of type **86** meridionally. In the formazan system, unlike the azo system, the plane of the anellated 6/6-rings in the octahedron stays almost planar. Twisting of the aromatic groups does not occur during metallization and there is therefore no loss of color intensity. Compounds of type **85** have an even larger absorption area in the UV – visible spectrum than their metal-free precursors [178].

Tridentate formazans form 1 : 1 complexes with divalent metal salts:

X = COO, O

These coordinatively unsaturated complexes can undergo coordination reactions with compounds having a free electron pair (particularly pyridine, amines, ammonia, and water). Coordination is associated with a marked hypsochromic color change. For example, the ligand-free nickel complex **87** is green and its pyridine adduct **88** is violet [180].

87 **88**

The coordinatively unsaturated complexes are even less soluble in organic solvents (e.g., diethyl ether, benzene, chloroform) than their saturated equivalents. The magnetic moment of copper complexes of formazans with a 2-hydroxyaryl substituent at N_1 is very low (1.44 BM) compared to the expected value for copper(II) complexes with an unpaired electron and strong covalent bonding. The low solubility and magnetic moment suggest that dimerization occurs with the formation of a saturated dinuclear complex **89**:

The saturated pyridine adduct **90**, which does not dimerize, has a magnetic moment of 1.7 BM. The copper complex **91** has an even higher magnetic moment of 1.81 BM [181].

89

90

91
[*69239-84-5*]

Quadridentate Formazans. Formazans with two complex-forming groups in the 2- and 2′-positions of the N_1- or N_5-aryl substituents are potential quadridentate ligands. They form 1 : 1 coordination complexes with four- and six-coordinate metals:

X, Y = O, COO

L = H_2O, NH_3, pyridine

The complexes assume a tetragonal planar structure so that two ligands can occupy free coordination sites at the apices of an octahedron.

WIZINGER and coworkers, who first produced the nickel and copper complexes [160], were not sure whether the complexes were of a bicyclic or tricyclic nature. The 1,5-bis(2-hydroxyphenyl)-3-cyanoformazan derivative of the copper complex **92** probably exists as a tricyclic structure because of the increased acidity of the phenolic hydroxyl group.

92 [*36090-18-3*]

Complexes with one or two carboxylic groups in the 2- or 2,2′-positions of the aryl substituents, however, appear to be bicyclic. Thus, a hydrate was obtained on reaction of 1,5-bis(2-carboxyphenyl)-3-cyanoformazan with copper acetate [182]. The coordinated water could not be removed by drying and produced a broad band in the IR spectrum at 3450 cm^{-1}. The copper complexes of formazans containing carboxyl groups **93** were then assigned the following structure:

X = O, COO
93

In the patent literature there are indications that the structure of copper complexes of the 2-hydroxy-2′-carboxylic acid type can be modified. After coupling and metallization, lightfastness, color intensity, and color quality can be improved by stirring the reaction mixture for 2 h at low pH [183]. The copper complex can be stabilized by refluxing for 15 h [184]. The coordinatively bound water may possibly be displaced by the carboxyl group in the 2-position during this aftertreatment, converting the dye to the tricyclic form **94** with a 5/6/6-ring system. Maybe a rearrangement proceeds simultaneously, in the course of which the coordinative bound migrates from N^1 to N^2 of the formazan structure to give the less strained form with a 6/5/6-membered ring configuration (**95**):

94

95

Another example of a tricyclic formazan structure with two six-membered rings and one five-membered ring is shown below (**96**), written in the customarily used 5/6/6-mode [226]:

96

Formazan-like structures with a 6/5/6-system are exemplified by **97** [227] and **98** [228]:

97

98

6.2. Production

6.2.1. Coupling of Diazonium Compounds with Hydrazones

The most common method for the production of formazans is the coupling of diazonium salts with aryl hydrazones in an alkaline medium, possibly an organic solvent:

For preparation, see [185, example 1]. The industrially important 1-(2-hydroxyaryl)-3-aryl-5-(2-carboxyaryl)formazans are obtained by this process. The corresponding bis(2-hydroxy) compounds cannot be produced by this method because 2-hydroxyaryl hydrazines are very unstable compared to 2-carboxyaryl hydrazines. For the production of bis(2-hydroxy)formazans, see Section 6.2.3.

6.2.2. Metallization

Bidentate formazans that are insoluble in water can be warmed with cobalt, nickel, and copper salts (preferably acetates) to form the appropriate metal chelates in solvents such as methanol, ethanol, acetone, and dimethylformamide.

Metal complexes of tri- and quadridentate formazans are much more stable. Metallization with divalent metal salts occurs rapidly at room temperature. On reaction with diazotized 2-aminophenols or 2-aminonaphthols, coupling and metallization with divalent metal salts can take place concurrently under the same conditions.

When coupling is complete, the dye is usually fully metallized: warming for a short time at 80 °C is only necessary in rare cases (see also Section 6.1.2). For production of cobalt(III) 1 : 2 complexes, a cobalt salt is generally added after coupling and warmed to 60 – 90 °C in a weakly alkaline medium. Reaction with chromium requires more severe reaction conditions; for example, the formazan and chromium formate are refluxed for 20 h to produce **99** [186]:

99
[100031-36-5]

Synthesis of the Copper Complex 100 [187, example 1]:

100

2-(3-Amino-4-hydroxyphenylsulfonamido) chlorobenzene (0.1 mol) is dissolved in 100 mL hot water, to which 21 mL of 10 mol/L NaOH solution is then added. After addition of 0.1 mol sodium nitrite, the solution is cooled to − 5 °C and then added to a well-stirred mixture of 42 mL concentrated hydrochloric acid, 100 mL water, and 50 g ice. After diazotization, excess nitrous acid can be destroyed with amidosulfonic acid. The diazonium salt suspension is neutralized with sodium hydrogen carbonate and combined with the weakly acidic solution of 0.1 mol of the hydrazone formed from 2-hydrazino-5-sulfobenzoic acid and benzaldehyde in 100 mL water. The reaction mixture is kept at 0 – 10 °C, and at pH 10 – 12 by dropwise addition of 10 mol/L NaOH. When coupling is complete, the pH of the brown formazan solution is reduced to 8 with hydrochloric acid, a dilute aqueous 0.1 mol/L solution of copper tetraaminosulfate is added and the solution is stirred for several hours. The copper complex formed is precipitated at 85 – 90 °C by the addition of sodium chloride, then filtered and dried. The powder produced is dark and colors wool in clear blue, fast tones.

6.2.3. Double Coupling of Diazonium Compounds with Compounds Containing an Acidic CH Group

Coupling with Compounds Containing an Activated Methyl Group. Some compounds with an activated methyl group can form symmetric formazans with strong diazo compounds by double coupling:

Examples of heterocycles with an activated methyl group are (I [188], II [189], III [190], IV [191]):

The formazans **101** produced from 2-methylbenzothiazolium salts exist as cations only in strongly acidic solution. When the pH is increased, they are converted into the uncharged olefinic disazo compounds **102**, and for the reaction with metal salts into the cationic formazan complexes **103** [190]:

Coupling with Compounds Containing an Active Methylene Group. During coupling of many methylene groups linked to two activating groups X and Y, the activating group X is exchanged for an azo group in the second coupling step. If the first coupling step is easier than the removal of the activating group X, then unsymmetric formazans can be synthesized by coupling the primary hydrazone formed with another diazonium compound:

X = COOH, $CONH_2$, CHO, CO-alkyl, CO-aryl, COCOOH, SO-CH_3
Y = X, COO-alkyl, CN, C = N-NH-aryl, SO_2-CH_3, SO_2-aryl

Only symmetrical formazans can be obtained, for example, from (I [192], II [193], III [194]):

I II

III

and from 4-oxopentanoic acid (levulinic acid), which couples to form the bisformazan **104** [195], [229]:

104

Unsymmetrical formazans can be prepared from the following compounds by stepwise coupling, preferably at differing pH values (I [193], II [196], III [197], IV [230]):

I

II

III

IV

Coupling with Compounds Containing an Active Trisubstituted Methane Group. Doubly activated methane compounds with aryl substituents can also be converted to formazans by elimination of both of the activating groups:

X = COOH, $CONH_2$, CHO, CO-alkyl, CO-aryl
Y = X, CN, COO-alkyl

H. ZIEGLER used coupling with diazotized 2-aminophenols to synthesize 1,5-di-2-hydroxyaryl-3-phenylformazans which are difficult to synthesize by the hydrazone method (see Section 6.2.1).

Ester and cyano groups generally resist substitution by arylazo groups and must first be hydrolyzed to produce carboxyl and carbonamide groups respectively, which can be more easily eliminated. Unsymmetrical formazans can be produced according to the following scheme :

Synthesis of the Copper Complex 105 [198, example 1]:

105

Ethyl phenylacetate (0.1 mol) and 14 mL 10 mol/L NaOH are stirred together at 0 °C in 300 mL water in the presence of an emulsifier. 14 g sodium carbonate and the diazonium salt from 0.1 mol 2-amino-6-chloro-4-nitrophenol are added and are coupled at < 25 °C. When the reaction is complete, the solution is neutralized with 10 mol/L hydrochloric acid, diluted with an equal volume of water, and brought to the boil; 80 mL 10 mol/L NaOH are added. The mixture is saponified for 10 min at 95 – 100 °C and neutralized again with 10 mol/L HCl. After cooling to 20 °C, the diazonium salt of 0.1 mol 1-amino-6-nitro-4-sulfo-2-naphthol is coupled in the presence of 0.1 mol copper sulfate and 26 g sodium carbonate. The coupling reaction is completed by heating to 60 °C. The resulting formazan is precipitated at 80 °C, filtered and dried. The dark powder colors wool, natural silk, and polyamide fibers an intense green tone with a blue cast.

A special process for the production of copper-containing 1,5-bis(2-hydroxyphenyl)formazans is based on the demethylating copperization of 1,5-bis(2-methoxyphenyl)formazans [199]. The method involves heating for a short time in pyridine, formamide, or dimethylformamide (see below).

In another process, the copper complexes are produced with alkylsulfonylamine as the complex-forming group [200].

Syntheses of formazans under phase-transfer conditions starting from hydrazones or from carbonyl compounds with active methylene groups are also possible. Azo coupling with aryldiazonium salts in two liquid phases occurs faster and in a better yield when catalyzed either by tetrabutylammonium bromide or dicyclohexano-18-crown-6 [231].

6.2.4. Oxidative Coupling of Azole Hydrazines with Hydrazones

Oxidative coupling of azole hydrazines with hydrazones takes place spontaneously in the presence of pyridine in air and is confined to the synthesis of heteroarylformazans, for example [201]:

X = S, N-alkyl
R^1 = alkyl, aryl, heteroaryl
R^2 = aryl, heteroaryl

Alkylation of 1,5-diheteroaryl-substituted formazans produces dehydroformazans with a cationic structure [202]:

This type of dye can also be prepared by oxidative coupling of azines with hydrazones [203].

6.3. Uses

Textile Dyes. Many metallized formazans are well suited as dyes for textile materials on account of their coloring strength and good fastness. The blue to blue – green copper complexes of quadridentate formazans are particularly important because of their color clarity, which is similar to that of anthraquinone dyes. They can also be combined easily with yellow, orange, and red azo dyes and therefore present a low-priced alternative to blue anthraquinone dyes for trichromic dying [204]. Copper complexes from quadridentate formazans are preferred on account of their high stability. Some dicyclic copper complexes of tridentate formazans also show good fastness and good application properties [205].

Wool and Polyamides. Water-soluble formazan complexes containing sulfonamide, alkylsulfonyl, or sulfonic acid groups possess a high affinity for nitrogen-containing fibers. As with acid dyes, they can be used to dye wool and polyamide in a neutral to weakly acid bath. Commercial dyes of this type are C.I. Acid Blue 267 and 297, and the 1 : 2 cobalt complex C.I. Acid Black 180, 13 710 **106**.

106 [*11103-91-6*]

As environmentally friendly alternatives to the Cr(III) and Co(III) metal complex acid dyes a range of 1:2 iron complex formazan dyes **107** was synthesized [232], which produce violet, blue, black and brown shades, furnishing dyeings on wool and polyamide with good wet and light fastness.

X = O, COO

107

Cotton. The most important formazan dyes are those containing reactive groups for dyeing and printing cellulose fibers. They are usually blue, occasionally green [206] copper complexes derived from 1-(2-hydroxyphenyl)-3-phenyl-5-(2-carboxyphenyl)formazans containing sulfonic acid and reactive groups. The following commercial products belong to this group: C.I. Reactive Green 15, Reactive Blue 70, 83, 84, 104, 157, 160, 182, 202, 209, 212, 216, 218, 220, 221, 226, 228, 235. The increasing importance of blue formazan dyes is mostly due to their suitability as a cheap constituent of triple dyes. The number of patents issued involving formazan dyes containing reactive groups was nearly 100 between 1985 and 1989 and nearly 65 between 1990 and 1994.

Analytical Reagents. As a result of their fast and intense color reaction, formazans can be used for the spectroscopic determination of a variety of metal ions. In a sensitive blue color reaction, Zn and Cu can be determined with the commercial product Zinkon [*135-52-4*] **108**. The detection limit for Zn ($\lambda_{max} = 625$ nm) is 0.02 ppm.

108 [*135-52-4*]

Some heterocyclic-substituted formazans are described as being very specific reagents. For example, **110** can be used for the detection of Co or Ni depending on the pH [207]; with **111**, depending on the pH, Sc or Sc and Y can be detected [208]. The formazan **112** is a reagent for Cu, Co, and Cd [209]; **113** a reagent for Hg [210]; **109** a selective reagent for Co [211]; and **114** a reagent for Cu and Ag [212]. Cu, Co, Ni, Cd, and Zn can be detected separately by colorimetry using **115** [213]. Microamounts of nickel in steel samples can be determined by spectrophotometry using **116** [233]. The anthryl formazans **117** give red Zn chelates and bluish green Cd chelates having a remarkably large difference of 110 nm in the wavelengths of their absorption maxima [234]:

109 [*51475-08-2*] R = H
110 [*78733-47-8*] R = SO_3H

111 [*94816-77-0*]

112 [*92829-23-7*]

113 [*114546-65-5*]

114 [*37704-00-0*]

115 [*72607-20-6*]

116 [157078-30-3]

Bioindicators. Water-soluble, colorless tetrazolium salts can be reduced to water-insoluble, deeply colored formazans. The reduction of tetrazolium salts in plant tissue at pH 7.2 was first demonstrated in 1941 [156]. Tetrazolium salts have since been used in biochemistry, cytochemistry, and histochemistry because of the irreversibility and great sensitivity of this reaction. They can be used to detect biological redox systems in blood serum, in living cells, tissues, tumors, and bacteria. Tetrazolium Blue [*1871-22-3*] **118** is a particularly sensitive reagent.

118

Indicator reactions are reviewed in [214], [215]. A more recent patent describes how cyanotetrazolium salts can be converted into fluorescent formazans for cytological diagnosis [216]. Another area of application is the fast determination of bacterial capacity in industrial wastewaters [217] and the determination of dehydrogenase activity in sludges [218].

Photoreagents. The conversion of tetrazolium salts into metallizable formazan dyes is used in color photography. Exposure of a photographic film to light results in the formation

R = 2-pyridyl, 2-quinolyl

117

of silver from a silver salt. When the film is developed with sodium thiosulfate in the presence of a tetrazolium salt, for example, a formazan is formed with the silver metal. The formazan is stabilized with transition metals and optically amplified [219]. In a silver-free method, the formazan is developed physically in a high-gain amplification process. The color of the photograph can be modified by varying the tetrazolium salt [220]. In another physical development process, the silver produced on the film is also amplified with formazan dyes [221]. Formazan dyes are also effective in photographic emulsions as antifogging agents [222]. Structure **119** represents discoloration-resistant photochromic formazan dyes, whose color change from red to yellow by irradiation wih a xenon lamp [235]:

119

Other Uses. Formazan dyes can also be used in many other areas. For example, porous membranes suitable for ultrafiltration can be modified with the reactive dye **120** [223]. Formazans of the formula **121** are used as dyes in inks for ink jet printing [224].

120

121

The cyclic formazans **122** are lithium-specific indicator dyes, useful for the quantitative colorimetric determination of lithium in biological fluids, e. g., blood [236]:

X = CN, NO_2
Y = CH_2-CH_2, CH_2, -CH_2-CH_2, CH_2-CH_2-O-CH_2-CH_2

122

Formazans are also used for transfer printing whereby the formazan derivative is on the transfer coating and the receiver coating contains zinc oxide as a chelating agent [225].

1. Introduction [1], [2]

Previously, glass formation was restricted to melts, usually of oxides, in which crystallization is very sluggish. However, with the advent of new solidification techniques with which cooling rates $> 10^6$ K/s can be achieved, a new class of material–the metallic glass–has emerged. Metallic glasses have been the focus of major research and development over the last fifteen years, including a continuing search for commercial applications.

As a starting point, it is convenient to separate solid materials into two rather large classes based on structural order: crystalline solids and amorphous solids. Crystalline materials are characterized by a periodic repetition in space of atoms grouped in a clearly defined structural element–the unit cell. The long-range repetition of the unit cell in three dimensions produces the crystallinity associated with metals. Crystalline materials thus give rise to X-ray diffraction patterns with sharp intensity maxima which are related to the periodic nature of the specific crystal lattice of the solid. In amorphous materials, there is no long-range periodicity, and the atoms are arranged more or less randomly. In amorphous solids there may be, however, regions of local order due to the topological and chemical constraints imposed by the close packing of atoms as the melt solidifies. This order is not repeated over large distances in the solid, and in general these regions are very localized and widely separated. Thus, X-ray diffraction patterns from amorphous materials have no sharp intensity maxima.

It is also apparent that the characteristics of cooling from the liquid state to the solid state differentiates crystalline from amorphous materials. In crystalline materials, as the melt is

10.1002/14356007.a16_335

cooled, the transition from the liquid state to the solid state is sharp and, under equilibrium conditions, takes place at a well-defined temperature with an appreciable release of heat. In amorphous materials, the transition from the liquid to the solid is very broad and can be quantified by the progressive increase in the melt viscosity towards a value so high that the material can be considered a solid. During this transition the atoms remain in approximately the same configuration as found in the liquid, and the glass can be considered as a supercooled liquid.

Amorphous solids can additionally be subdivided into two groups: glasses (inorganically based) and polymers (organically based). Inorganic glasses, such as fused silica or mixtures of silica with oxides of Al, Na, Mg, Ca, etc., comprise the oldest group of amorphous solids. Other glasses based on elements of groups 15, 16, and 17 also form glassy solids (e.g., chalcogenide glasses). When cooled from the melt, the silicates and chalcogenides do not crystallize. However, liquid metals and alloys do crystallize upon freezing. In the last twenty-five years, however, novel processing techniques have led to the development of amorphous metallic alloys. Unlike silicates and chalcogenides, it is very difficult to prevent metallic alloys from crystallizing unless the melts can be cooled at very high rates (i.e., $\geq 10^6$ K/s). At these high cooling rates, the liquid becomes supercooled and crystallization is suppressed. A metallic glass is thus formed. However, it must be remembered that these supercooled glassy metals only persist in metastable equilibrium; hence metallic glass alloys should be regarded as thermodynamically metastable. These alloys may remain in a particular metastable state indefinitely for kinetic reasons; however, they tend to evolve with time towards other amorphous configurations having lower free energies until an equilibrium state characteristic of the particular temperature is reached or until the crystalline phase is formed.

Even though metallic glasses exist in metastable equilibrium, they have generated considerable interest for two reasons. First, the fact that amorphous metallic alloys could be produced at all generated scientific curiosity. However, as experimental research proceeded, interest grew in understanding the solid state structure, the unusual mechanical properties, the liquidlike electrical properties, and the ferromagnetic properties of these amorphous metallic alloys [1]. In fact, metallic glasses have become an important commercial material (e.g., Allied-Signal Metglas) precisely because of their magnetic properties.

Table 1. Metal – metalloid and metal – metal metallic glass formers [1]

Groups ∗	Representative systems	Composition, atom %
Major Systems		
T^2 metal	Pd – Si, Co – P,	15 – 25 (X)
+ metalloid (X)	Ni – P – B	
T^1 metal +	Zr – Cu	30 – 65 Cu
T^2 metal (or Cu)	Ti – Ni	30 – 40 T^2
	Nb – Ni	40 – 65 Ni
Miscellaneous Systems		
A metal + B metal	Mg – Zn	25 – 35 Zn
Actinide + T^1 metal	U – V, U – Cr	20 – 40 T^1
T^1 metal + A metal	(Ti, Zr) – Be	20 – 60 Be

∗ A metal = Li, Mg groups; B metal = Cu, Zn, Al groups; T^1 metal = early transition metal (Sc, Ti, V groups); T^2 = late transition metal (Mn, Fe, Co, Ni groups) or noble metal; metalloid = B, C, Si, Ge, P

2. Structural Characteristics of Metallic Glasses

It is generally acknowledged that pure metals cannot be quenched from the melt into a metallic glass with the presently achievable cooling rates of $10^6 - 10^8$ K/s. This means that all metallic glasses are in fact alloys containing two or more elements. No theory at present is capable of predicting the composition of a metallic alloy that is likely to be amorphous upon solidification from the melt. However, experimental results suggest some general guidelines for the development of amorphous metallic alloys [2].

Many glassy alloys contain both a strongly metallic element, such as Cu, Ag, Au, Fe, Co, Ni, Pd, or Pt, and a nonmetallic element (i.e., metalloid) of valence 3 (B), 4 (C, Si, or Ge), or 5 (usually P) [2]. There are exceptions to this general guideline, most notably the following binary alloys: Cu – Zr, Nb – Ni, Ta – Ni, Y – Cu, and Ti –Ni [1]. Table 1 contains a classification scheme for metal – metalloid and metal – metal metallic glass alloy systems as well as some miscellaneous systems.

Ternary metallic glass alloys contain either two metals and one metalloid (e.g.,

Pd – Ni – P) or one metal and two metalloids (e.g., Fe – P – B). In both cases the sum of the metallic elements amounts to 70 – 85 atom %, leaving 15 –30 atom % metalloid [2].

Metallic glasses containing up to 90 atom % aluminum were produced independently in Japan and the United States. These glassy aluminum alloys, unlike previous metallic glass alloys, have a low density, resulting in high specific strengths [3], [4].

2.1. Glass Formation and Crystallization

If an appropriate liquid is quenched rapidly enough to bypass normal solidification then a metallic glass is formed. The resulting metallic glass is inherently metastable and, at temperatures well below the melting point of the alloy, the glass can transform into one or more crystalline phases. It is therefore instructive to understand how metallic glasses form and then transform to their crystalline counterparts.

Upon melting, a metal or alloy loses its three-dimensional lattice arrangement of atoms. All long-range order is destroyed and the atoms subsequently vibrate about positions that constantly interdiffuse in the liquid state. During melting, the crystal and the liquid are in equilibrium. For pure metals, the enthalpy, entropy, and volume undergo a discontinuous change (i.e., enthalpy, entropy, and volume increase). As a liquid well above the melting temperature, the melt is in a state of internal equilibrium, and its structure and properties are independent of its thermal history.

During solidification, a liquid must be undercooled below its equilibrium crystallization temperature in order to surmount an energy barrier to nuclei formation. The degree of undercooling needed to form nuclei depends on the initial viscosity of the liquid, the rate at which the viscosity increases with decreasing temperature, the temperature dependence of the free energy difference between melt and crystal, the volume density and efficacy of heterogeneous nucleating particles and the imposed cooling rate [5]. The growth rates of crystals in metallic melts are quite rapid once nuclei have formed, and rapid recalescence occurs in those regions where the rate of heat removal to the surroundings is small.

Figure 1. Variation of volume V, viscosity η, specific heat C_P, and free energy G, with temperature for crystalline and amorphous phases [1]

When a liquid is cooled rapidly by heat removal to a sink, the influence of heterogeneous nucleants is delayed for kinetic reasons. As the cooling rate is further increased, undercooling is enhanced and recalescence decreases. Thus, the temperature range over which crystallization proceeds becomes increasingly narrow. This leads to a refinement of the microstructure, an extension of solute solubility, and to the formation of metastable crystalline phases. When

the cooling rate is sufficiently fast, crystallization is completely suppressed because of insufficient time for the development and growth of nuclei. In this case the shear viscosity of the melt η increases continuously, as shown in Figure 1.

Although the driving force for nucleation continually increases, the rapid decrease in atomic mobility of the melt opposes nuclei formation and dominates at high undercooling. Eventually, the atomic configurations of the liquid departs from equilibrium and becomes homogeneously "frozen" at the glass transition temperature T_g. The structural freezing to the glass state is, by convention, considered to occur when the viscosity of the melt reaches 10^{13} poise. No unique glass structure exists in reality because the temperature and structure at which departure from configurational equilibrium occurs depends on the cooling rate. Thus, T_g and the glass structure are dependent on the cooling rate.

Figure 2. TTT diagram of glass formation and crystal growth in an undercooled melt [6]
(a) Fast cooling to form a glass; (b) Isothermal heating of glass (i.e., $T < T_g$) giving crystallization at time t_x; (c) Slow heating of glass producing crystallization at T_x

The glass-forming ability of a material is determined by the kinetics of the nucleation process and of the early stages of crystal growth [6]. This is illustrated by a TTT (time – temperature – transformation) diagram (Fig. 2). If the liquid is quenched from above T_m (i.e., the absolute melting temperature) to well below T' (i.e., the temperature at which the crystallization rate is a maximum) in a time t_{min} (i.e., the minimum time for crystallization), the undercooled liquid is retained, and at T_g, the configuration is frozen to form a glass. At room temperature, the time for crystallization of a glass is very long. If the glass is heated to a temperature $T < T'$ and held isothermally for a time t_x, it will begin to crystallize. Alternatively, if the glass is heated slowly from room temperature, crystallization begins at T_x and increases with increasing heating rate. In actuality, there are a number of crystallization reactions. Most metallic glasses initially crystallize into one or more metastable phases before crystallizing into the equilibrium phase.

Crystallization of metallic glasses does not occur at a unique transformation temperature. There are a range of temperatures at which crystallization can occur, although it is standard practice to define the crystallization temperature of a metallic glass as the temperature at which spontaneous crystallization begins as the glass is heated at a constant rate from room temperature. Usually the crystallization temperature T_x is defined as the onset temperature or the peak temperature of the first exotherm of a differential scanning calorimeter (DSC) scan. Upon crystallization, the density of a metallic glass increases by ca. 1 %. The enthalpy of crystallization is ca. 5 kJ/mol and represents about half the latent heat of melting [7]. The crystallization temperature for most metallic glasses lies between $0.4\,T_m$ and $0.65\,T_m$. Absolute values of T_x vary from ca. 400 K for magnesium-based glasses to 1200 K for glasses based on refractory metals. Ferromagnetic iron-based glasses possess T_x values near 700 K [7].

A number of factors increase the crystallization temperature in metal – metalloid glasses. These factors include low overall electron/atom ratios, the large atomic size difference between constituent transition metals, and the different structures of the stable metal – metalloid crystalline phases that occur in an alloy system [7].

The crystallization mechanism which occurs in a metallic glass can depend upon its composition. The following reactions have been observed:

1) polymorphous crystallization,
2) eutectic crystallization,
3) primary crystallization, and
4) separation into two distinct glassy phases.

Polymorphous crystallization occurs when the glass transforms into the crystalline phase

with no change in composition. As an example, the crystal phase in an iron – boron glass is usually Fe_3B although the equilibrium phase is Fe_2B [8].

Eutectic Crystallization. In this transformation reaction the glass forms two phases which grow in a coupled fashion. There is no overall change in composition from glass to eutectic colony. In an $Fe_{40}Ni_{40}P_{14}B_6$ glass, the crystal contains fine lamallae of iron – nickel austenite and the metastable $(Fe,Ni)_3PB$ phase. Growth of the dominant eutectic colonies is initiated by homogeneous nucleation of the boride phase, after which the iron-rich phase nucleates without difficulty [9].

Primary Crystallization. In this reaction, the first crystals to form have a composition different from the glass (e.g., nearly pure Al crystallizes from an Al – Fe – Gd glass; see Fig. 3) [1]. The rate of growth of the crystals is determined by the kinetics of the diffusion of rejected solute (i.e., Fe and Gd) away from the aluminum crystallite into the remaining glass. The solute-enriched glass then undergoes a polymorphous transition to another crystalline species.

Figure 3. High resolution electron micrograph of $Al_{90}Fe_5Gd_5$ metallic glass after annealing at 175 °C for 150 min
The periodic region is an aluminum crystallite along the [110] direction; the remaining area is glassy [3]

Separation into Glassy Phases. For example, a $Zr_{36}Ti_{24}B_{40}$ glass separates into very distinct but glassy phases below T_x, with each glassy phase crystallizing separately [10].

Crystallization kinetics usually follow the Avrami equation for solid state nucleation and growth processes [11]

$$x(t) = 1 - \exp\left[-b\,(t-t_0)^n\right] \tag{1}$$

where $x(t)$ is the fraction crystallized in time t, t_0 is the incubation time, b is a temperature dependent rate constant [equal to $b_0 \exp(E_x/kT)$], and n is an exponent which varies from 1.5 to 4.0 [6]. The activation energy E_x in the crystallization process, which incorporates the activation energy for both nucleation and growth of the crystallite, varies from 40 to 400 kJ/mol [7].

Once crystals are nucleated in the metallic glass, growth proceeds in the conventional manner. For example, during polymorphous crystallization, in which diffusion is not necessary, the growth rate is independent of time and increases exponentially with increasing temperature. In primary crystallization, the process is diffusion controlled. The crystal dimensions are thus proportional to the square root of time. Eutectic crystallization is also diffusion controlled. Depending on the glassy alloy, the diffusion necessary to partition the solute between the crystalline phases may occur at the crystal – glass interface or in the glass ahead of the growing crystal. The spacing between phases is independent of growth rate, unlike conventional eutectic and eutectoid transformations [7].

2.2. Structure

In metallic crystals, determining the structure consists of identifying the coordinates of all atoms in the unit cell. For a glass, however, the structure can only be described on a statistical basis. Glasses do not possess a unit cell, and the local environments of different, chemically identical atoms may vary.

The determination of glassy structures resolves itself into two complementary tasks: determining a radial (or pair) distribution function (RDF) and modelling [1], [12]. In principle, the RDF does not provide a complete, unambiguous description of the glass structure. It constitutes an important test of the validity of a proposed structural model, which in turn must be augmented by tests of other properties (e.g., determination of macroscopic density, and the re-

sults of Mössbauer spectroscopy, nuclear magnetic resonance, and positron annihilation studies) [13].

Several models for metallic glasses deserve mention [14]. The first model, the Dense Random Packing (DRP) model, was developed by BERNAL, initally for liquid structures [15]. GASKELL [16] has proposed an alternative model based on prism packing which mimics the smallest identifiable units of a stable crystalline phase. A third model starts with the DRP model but incorporates the effects of chemical ordering [1], [12].

Figure 4. Polyhedra formed from dense random packing of hard spheres [15]

Bernal's empirical model [15] originally referred to the DRP of hard spheres of equal diameter. The packing was based on physical experiments with steel balls kneaded in a rubber bag. The packing of the spheres was statistically reproducible and consisted of a number of different polyhedra (Fig. 4). The small polyhedra (i.e., the tetrahedra and octahedra) make up the majority of structural units, although the frequency ratio of polyhedra is subject to dispute. For some metallic glasses, there is respectable agreement between the computed RDF and that deduced from diffraction experiments. However, in the case of an Ni – P glass, the computed RDF ignores the P atoms. A second problem with Bernal's approach is the use of "hard" spheres in the model. This model has been modified to account for these difficulties, and the replacement of "hard" spheres with "soft" spheres has led to better agreement between the modelled and "observed" RDF [17]. Even with these refinements, Bernal's approach suffers from numerous approximations and other difficulties.

Figure 5. (A) Trigonal prismatic packing of transition metal atoms (hatched) and metalloid atom (solid), as found in Fe_3C or Fe_3P; (B) In a glass the prisms can be connected in various configurations after relaxation has occurred, of which this is the most important example [16]

In attempting to reconcile a deficiency in Bernal's model of the glass structure, GASKELL [16] proposed a prism packing model (Fig. 5) analogous to the network model used for oxide glasses. In metal – metalloid glasses with about 20 % metalloid atoms, GASKELL calculated that the metalloid diameter must be ≤ 0.48 of the metal atom diameter. It had been assumed that metal – metalloid glasses are stabilized by the insertion of small atoms into the larger structural voids in the assembly of large atoms. However, only carbon and boron can physically occupy these voids without lattice distortion, even though phosphorus, silicon, and arsenic are effective glass stabilizers. In the Pd_3Si glass, the linkage of prisms among themselves is refined by computer approximations in order to minimize atomic overlap. The resulting densities and RDF's agree well, and GASKELL proposed that the modelling procedure can apply to many metal – metalloid glasses. Further confir-

mation of the network model has been obtained for $(Ru_{84}Zr_{16})_{1-x}B_x$ glasses ($0.40 < x < 0.53$) [18]. With this high metalloid content, no DRP model gives even moderate agreement with the diffraction data. However, a form of irregular packing based on the Ru_2B crystal structure provides good, though not perfect, agreement to observed RDF's. This structural model accommodates more easily the high metalloid concentrations than either the hard or soft RDP models.

The third approach models metal – metal glass alloys [1], [12]. This concept is based on chemical short-range order (CSRO) where the nearest neighbor identities are not randomly determined. The philosophy behind this approach contends that a preexisting single component model incorporates the fundamental packing constraints in a dense, noncrystalline structure. With the topology precisely determined, complete data are available which allow the labelling of A and B atoms in a manner consistent with the desired local order. Different combinations of A and B labelling can be analyzed by allowing statistical variations in the topological and metrical perfection of the local ordering scheme. Thus relaxation calculations can be performed with periodic boundary conditions. A $Mg_{70}Zn_{30}$ metallic glass [19] has been studied by means of CSRO with potentials developed from pseudopotential theory [20].

2.3. Relaxation

A metallic glass is a metastable structure in which large-scale rearrangements are difficult due to low atomic mobility. The exact structural state developed in the glass is directly related to its cooling rate. If a glass is subsequently annealed below T_g, the structure will evolve toward a more stable state (e.g., toward the structure of the thermodynamically "ideal glass"). The relaxation process involves the reduction in free volume and changes in the chemical identity of nearest neighbor atom pairs. Associated with relaxation of the glassy structure is a change in its physical properties.

When a metallic glass relaxes, its density increases by ca. 0.25 % and its enthalpy decreases by ca. 1 kJ/mol [21]. The physical properties of the glass also change, with elastic modulus, Curie temperature, and viscosity increasing, while the thermal resistivity, diffusivity, and fracture toughness decrease [1], [21].

Although metallic glasses have no long-range atomic periodicity, they possess a degree of short-range order (i.e., local atomic coordination). Relaxation thus causes changes in the short-range order (SRO) and the defect distribution within the glass. When rapidly cooled from the melt, the solid glass is highly disordered. Upon annealing below T_g, various structural defects are removed and the SRO increases. This leaves a new structural configuration in metastable equilibrium at the specific annealing temperature. This process can be repeated at different annealing temperatures, and at each temperature the SRO changes to reflect the new metastable equilibrium condition. Two accepted types of microstructural changes are associated with changes in SRO [1], [21]:

1) topological short-range order, and
2) chemical short-range order.

Topological Short-Range Order (TSRO). Changes in TSRO constitute a more efficient packing of the constituent atoms irrespective of their chemical identity. This process effectively eliminates and/or redistributes the free volume within the structure. As a result, the density of the glass increases. Since TSRO involves the cooperative rearrangement of atoms over relatively large distances, this process is expected to occur slowly.

Chemical Short-Range Order (CSRO). Changes in CSRO occur upon rearrangement of individual species on the atom sites. These changes occur rapidly since long-range movement of atoms is not necessary.

Although the two ordering effects have been treated separately, in practice they are interrelated because changes in SRO are likely to involve both topological rearrangement and chemical ordering.

Relaxation processes affect the physical properties of metallic glasses to a great degree. For example, the elastic modulus of a metallic glass may change by 10 % upon relaxation. Since the quenching rate can change the structure and properties of the glass, the thermal history of a metallic glass is very important. Additionally, it is generally not possible to standardize the structural state of metallic glasses,

following different quenching rates, by a relaxation annealing below T_g. However, the measured properties will be more consistent if the metallic glass is relaxed as fully as possible prior to property measurements.

3. Processing

The critical processing step in producing metallic glasses is the quench from the liquid state. The quench rate must be very fast ($> 10^6$ K/s) to freeze in the desired metastable structure; therefore, rapid heat removal from the bulk is needed. This requires that any cooling process has a sufficiently high heat transfer coefficient at the interface of the liquid metal and the cooling medium and that the material possess a thin cross section in order that heat be rapidly conducted out of the metal. Another important factor in the preparation of rapidly quenched materials is undercooling the melt so that subsequent recalescence does not cause morphological destabilization of the material.

In removing heat from the bulk liquid metal alloy, it is important to maximize the contact area between the liquid and the cooling medium by rapidly increasing the surface area of the liquid alloy. This basic principle has led to a number of procedures for producing metastable alloys [1], [22].

3.1. Sputtering and Evaporation [23]

Sputtering and evaporation methods build metallic glass alloys atom-by-atom. Sputtering and evaporation techniques depend on the deposition of a vapor on cold substrates (often cooled to liquid nitrogen or liquid helium temperatures). In essence, these methods require that the kinetic energy of the condensing atom exceeds the binding energy of the atoms in the substrate surface. Sample preparation by these means is very slow (i.e., 20 µm/h) and is very sensitive to deposition conditions. For example, the presence of impurity atoms such as oxygen facilitates the formation of an amorphous atomic structure [24]. However, because this method maximizes the surface-to-volume ratio, very high quench rates may be achieved (10^8 K/s), allowing the formation of metallic glasses that cannot be produced by other melt quenching techniques.

3.2. Chemical Deposition and Electrodeposition

Various metal – metalloid amorphous alloy systems have been prepared by chemical deposition and electrodeposition. The final alloy composition depends on the deposition conditions and bath composition during sample formation. Deposition rates of ca. 0.1 mm/h are typical [25]. Most alloys produced by these methods to date have consisted of Fe, Ni, and/or Co with P, B, or S.

3.3. Ion Implantation

Ion implantation, which has an effective quench rate of 10^{14} K/s, allows a wide variety of atomic species to be introduced into the surface of many materials. This technique has produced amorphous materials that are virtually identical to alloys of the same nominal composition made by more conventional rapid solidification techniques. For example, nickel films can be amorphized by phosphorus ion implantation and are identical to films produced by evaporation or electrodeposition [26]. However, self-ion bombardment (e.g., Ni^+ into Ni) never generates a stable glassy structure. Ion implantation is attractive because it allows a degree of freedom from the compositional restrictions imposed by constitutional phase diagrams, although similar composition rules for metallic glass formation seem to apply for both implanted and conventionally quenched alloys. In essence, ion implantation is a surface modification technique because the distance of ion penetration is linked to the energy loss sustained by the penetrating ion. Single-stage ion implantation modification remains viable only for thin samples.

3.4. Splat Quenching

The gun technique developed by Duwez [27] was probably the earliest rapid solidification method used to produce metastable crystalline and amorphous alloys. In the gun technique,

a molten alloy is atomized by expulsion from a shock tube. The molten alloy droplets are then propelled against a substrate having a high thermal conductivity. The gun technique probably achieves the highest cooling rates of all splat quenching techniques for the very thin regions of the foil. However, the resultant samples are irregular in thickness (i.e., 0.1 – 50 µm) and are very small. As a result, other techniques have evolved from the gun method. For example, the piston and anvil [28] and twin-piston (Fig. 6) [29] methods rapidly flatten and quench molten alloy droplets between impacting substrate surfaces, leading to a more uniform splat. The arc-hammer method uses a water-cooled hearth to quench an arc-melted button of material struck by a hammer [30]. Modifications of these techniques include the use of better substrate materials (e.g., diamond [31]) and quenching techniques (e.g., magnetically driven substrate platens [32]). All splat quenching methods produce to a certain extent foils of irregular shape and variable thickness. These techniques are not suitable for producing large quantities of material.

Figure 6. Twin-piston splat quenching with levitation induction melting

3.5. Spray Deposition or Plasma Spraying

Variations of melt droplet spraying and deposition have been used to fabricate rapidly solidified materials. One variation involves the injection of a molten alloy into a hot plasma flame which forms splats upon impact with a high-conductivity substrate [33]. Another modification involves the use of a rotating wheel substrate which substantially increases sample yield [34]. Spray techniques combine melting, quenching, and compaction into a single processing step [35].

3.6. Melt-Spinning

Melt-spinning (Fig. 7), or the production of filaments, ribbons, or tapes of rapidly solidified material, has the advantage of producing products in continuous form. Making continuous rapidly solidified materials from the melt improves both the sample geometry and the quench rate geometry.

Figure 7. Melt-spinning with cooling on a metal drum
a) Melt; b) Induction coil; c) Ribbon

Filaments of circular cross section can be made by expelling the molten alloy through a circular orifice [36]. Melt-jet stabilization, solidification, and cooling are controlled by the quenching media [37], either gases [38] or liquids [39]. A solid substrate can also be used to quench the molten alloy, but this results in a quasi-circular cross section. Such processes include melt drag [40], crucible [41], and pendant-drop melt extraction [42].

Metallic ribbons have been made for over 80 years by allowing a stream of molten alloy to flow onto a rapidly moving substrate [43]. Chill block melt-spinning (CBMS) [44] utilizes the impingement of a jet of molten alloy from a circular orifice onto a rapidly moving substrate to produce a continuous ribbon. The puddle that results from the impingement of the melt jet serves

as a local reservoir from which the ribbon is continuously formed and chilled. Both the initial quench rate ($10^5 - 10^8$ K/s) and the final ribbon geometry depend upon the nature of the melt puddle. Ribbons 20 to 200 µm in thickness usually result from this technique. A smooth, unchanging puddle produces ribbons with smooth edges and surfaces [45]. Typical substrate surfaces are the inside of drums [46] or wheels [47], the outside of wheels [48], between twin-rollers [49], and on belts [50].

The difference between ribbons and tapes lies in the width of the resultant rapidly solidified material. The use of a slit several centimeters or more in width replaces the circular orifice in the CBMS method [51]. The use of a planar melt jet is difficult due to the destabilization of the stream that results from the high surface tension and low viscosity of the molten alloy [52]. As a result, planar flow, or strip, casting of molten metallic alloys has been developed in which the melt nozzle is held very close to the moving substrate [53]. This reduces perturbation of the melt on the substrate and thus results in the formation of rapidly quenched tapes of various widths.

3.7. Electron-Beam and Laser Surface Melting [54]

Rapid quench rates (i.e., $4\times10^4 - 5\times10^6$ K/s) have been generated by melting a thin layer on the surface of a suitable substrate material. Electron and laser beams are very efficient in melting small surface areas rapidly and continuously because of the high energy densities (100 kW/cm^2) they generate. For example, 400 µm thick amorphous surface layers have been created on a $Pd_{91.7}Cu_{4.2}Si_{5.1}$ substrate [55]. Aside from forming amorphous surface layers, these techniques can be used to form new surface compositions by melting thin films [56] or by continuously feeding alloy wire or powder onto the substrate surface [57].

3.8. Atomization and Comminution [58]

Atomization and comminution techniques are efficient in producing rapidly solidified powders having a refined microstructure and grain size as well as homogeneous, stable phases. Atomization is a process whereby powder particles are formed from the quenching and solidification of discrete droplets of liquid metal. Comminution is the chopping or comminuting of rapidly solidified ribbons or tapes of amorphous alloys.

Atomization techniques include ultrasonic gas atomization (10^5 K/s) [59], water atomization ($10^5 - 10^6$ K/s) [60], gas – liquid atomization (10^6 K/s) [61], centrifugal atomization ($10^5 - 10^6$ K/s) [62], roller atomization (10^5 K/s) [63], and spark erosion ($10^6 - 10^9$ K/s, depending on powder size; i.e., the smaller the powder particle the faster the cooling rate) [64].

The final product of all atomization and comminution processes is a powder which must ultimately be consolidated into a useful shape. For example, dynamic or explosive compaction has been used to consolidate powder while retaining the amorphous state [65]. Other consolidation techniques include warm die pressing and warm extrusion. However, whenever an amorphous material is heated, devitrification is always a problem. While much is known about processing crystalline powder alloys, creating amorphous powder materials is still a relatively underdeveloped area of research.

4. Physical Properties of Metallic Glass Alloys

4.1. Mechanical Properties

Metallic glasses exhibit mechanical properties quite different from those of crystals. The disordered atomic structure increases the flow resistance in metallic glasses so that the ratio of Young's modulus to yield strength E/σ_y is typically about 50, which approaches the theoretical strength of these materials. The fracture strength of iron-based glasses can be as high as 3.4 GPa. The average ratio of hardness to yield strength is about 3, which is also observed for crystalline metals, but the elastic stiffness is lower than that of its crystalline counterparts. The ductility of glassy metals depends strongly on the stress state. For example, metallic glasses behave in a ductile manner when bent (with strains as high as 100 %), but they are macroscopically brittle in tension. The fracture toughness in metallic glasses is also higher than in conventional

glasses; and it is higher in comparison with metals if based on strength.

4.1.1. Elastic Properties

A detailed review of metallic elasticity is given in [66]. In general, the elastic or shear modulus of a metallic glass is less than that of its crystalline counterpart. Typical experimental values for the ratio of the crystalline to amorphous moduli lie in the range 1.2 to 1.4. The lower modulus in the metallic glass is associated with its lower density and the presence of "loose" sites in the amorphous structure [67]. The moduli increase irreversibly after thermal treatment and correspond to structural relaxation during thermal treatment [68].

Poisson's ratio ν for metallic glasses is about 0.4. This is high when compared to metals and alloys ($\nu \approx 0.33$) and nonmetallic glasses ($\nu \approx 0.25$).

Generally, glassy metals exhibit isotropic elastic behavior by virtue of their random disordered atomic structure; however, anisotropy can be induced in certain ferromagnetic metallic glasses by magnetic annealing. Such anisotropic behavior is relatively minor and elastic isotropy is a reasonable assumption for most cases.

4.1.2. Anelastic Behavior

Metallic glasses exhibit time-dependent stress – strain behavior. This behavior results from the stress-induced adjustment of the glass as it passes from one state of metastable equilibrium to another, in response to the applied stress.

Relaxation processes include thermoelastic rearrangement, atomic diffusion, and magnetoelastic interaction. The thermoelastic effect involves the adiabatic temperature change in the glass due to applied stress; such a change causes a strain increment and results in a change in modulus.

Elastic relaxation in metallic glasses can be induced by atomic diffusion as in crystalline solids; however, in amorphous solids, the concept of a discrete lattice site is replaced by generalized concepts of free volume and "loose" sites. The reversible motion of "loose" sites can be envisioned as a micromechanism of anelasticity in glassy metals [69].

Figure 8. Young's modulus of $Fe_{75}P_{15}C_{10}$ metallic glass after various thermal annealing conditions [66]

4.1.3. Magnetoelastic Interactions

Certain ferromagnetic metallic glasses exhibit a ΔE-effect. The ΔE-effect refers to the change in the elastic modulus E with changing magnetization states. The ΔE-effect in metallic glasses can be large and is readily demonstrated at room temperature with low to moderate fields. Figure 8 shows how E varies with temperature for a Fe – P – C glass for different magnetic states. These curves represent the elastic modulus for the saturated magnetized condition (E_S), for the demagnetized condition (E_D), and for an intermediate level of magnetization where the modulus exhibits a minimum value (E_{min}). The uppermost curve depicts E after crystallization annealing at 450 °C. After crystallization, the modulus increases substantially and the ΔE-effect disappears. However, the loss of the ΔE-effect is not associated with a loss of ferromagnetism. The ΔE-effect depends in part on the alloy composition and prior treatment, as well as on the magnetization and temperature. Magnetoelastic effects do not arise from large magnetostriction, but rather reflect the absence of strong restraints to the motion of domains. It has been found that the change of elasticity at the intermediate state of magnetization is caused by a rotation process of the magnetic moment [70] and domain boundaries [71]. It is believed that domain movement

with applied stress produces the ΔE-effect responsible for anelasticity [66].

4.1.4. Plastic Properties

Basically, plastic flow in metallic glasses occurs in two ways: homogeneously and inhomogeneously. Homogeneous flow, in which the glass deforms uniformly, occurs at low stresses ($\tau < \mu/50$, where τ is the shear stress, and μ the shear modulus) and usually is observed in creep experiments. Inhomogeneous flow in which the strain is localized in a shear band, occurs at high stress ($\tau > \mu/50$) and low temperatures ($T < 0.7\,T_x$).

Homogeneous flow in metallic glasses is significant during deformation at elevated temperature. At sufficiently low stresses ($\tau < \mu/100$), the flow is Newtonian viscous ($\dot{\gamma}\,\alpha\,\tau$, where $\dot{\gamma}$ is the strain rate) and is characterized by a shear viscosity η ($\eta \equiv \tau/\dot{\gamma}$). At higher stress, the shear stress – strain rate relation is nonlinear and can be described as $\dot{\gamma}\,\alpha\,\sinh(A\,\tau)$, where A is a factor associated with the temperature and material properties.

The microscopic mechanisms for homogeneous flow have been reviewed in [72]. These mechanisms are based on models of free volume, configurational entropy, microscopic shear transformation, structure relaxation, and isoconfigurational flow.

The free volume and configurational entropy models have been used to interpret flow at high temperature ($T > T_g - 20$). The former model accounts for the temperature dependence of flow by examining changes in relative free volume in the glasses, while the latter explains the temperature dependence by considering changes in the size of the rearranging region.

For flow at low temperature ($T < T_g - 20$), structural relaxation is the most important micromechanism. The atomic structure deviates from the configuration required for equilibrium due to rapid cooling during glass formation. This "frozen" atomic configuration is allowed to approach its equilibrium state at a temperature slightly below T_g. The subsequent viscosity increase during isothermal annealing can be interpreted as an increase in structural order, which results in a decrease in the atomic defect density in the flow region, which is related to flow resistance. At high heating rates, ductility decreases less rapidly as a consequence of structural relaxation than it does for low heating rates [73]. Therefore, by controlling the composition and thermal processing, high homogeneous plastic deformation can be achieved.

Inhomogeneous Flow. At high stress levels, plastic flow in metallic glasses occurs in highly localized deformation shear bands. The strains sustained in individual shear bands are exceptionally large. There is evidence that these bands accommodate shear strains of ca. 10, with shear band width as narrow as 2 – 5 nm [74]. The number of shear bands and their orientation are determined by the kinematic constraints of the deformation process (e.g., they are different for uniaxial compression, bending, rolling, drawing, and localized indentation). Multiple shear bands are observed to form due to mechanical constraints which prevent catastrophic shear instability. Figure 9 shows an example of multiple shear band development in a Al – Fe – Gd glass upon shearing of the ribbon surface.

Figure 9. Primary and secondary shear bands produced by complex bending [3]

The appearance of intensely localized shear flow is sufficient to demonstrate the absence of work hardening in metallic glasses. As a consequence, the deformation of metallic glasses loaded in uniaxial tension is mechanically unstable, and tensile failure occurs almost immediately after yield. Therefore, the tensile fracture strength of a metallic glass is almost identical to its yield strength, and the tensile fracture strain is equivalent to that of brittle materials. In contrast, when a shear instability is avoided and a multiple shear configuration can be developed, the ductility of metallic glasses is remarkable (e.g., 5 % in compression and 100 % in bending).

There are two primary micromechanisms which explain the localized shear band deformation phenomena: the dislocation model and the fluid layer model.

Dislocation Model. Slip lines are observed to terminate inside an amorphous metal, and the boundary which separates the slipped from the unslipped regions can be defined as a "dislocation" in a metallic glass. Since the slip vector (both direction and magnitude) may not be constant along the dislocation line, it is called Somigliana dislocation [75].

The topology of forming localized dislocations in amorphous systems has been investigated by CHAUDHARI et al. [76], [77]. It was determined that stress fields, characteristic of both screw and edge dislocations, can be found in an amorphous solid.

The existence of dislocations is supported by the reversible nature of shear band formation. For example, a shear band can be sheared in a reverse direction [78]. This reversibility cannot easily be removed by annealing, and it persists until the material is embrittled by crystallization.

Fluid Layer Model. The viscosity of a metallic glass can decrease due to the dilatation at a stress concentrator, such as a microcrack [79]. The free volume, and hence the atomic mobility of a viscous fluid layer, can be generated in the shear band. After shear band initiation in the viscous layer, subsequent softening is sustained by strain-induced disordering. That is, the deformation process continually disorders the material in the shear band at a rate faster than structural relaxation processes can restore it. In this model, disordering is assumed to be a shear-induced, free-volume creation process. This results from atoms pushing their neighbors aside at high stress levels. This process is balanced by an ordering process during which free volume is annihilated [80]. Such creation and annihilation processes establish a steady state, in which the free volume, and hence the viscosity, is a function of the applied stress. This model accounts for the strain rate insensitivity during inhomogeneous flow.

Experimental support of the fluid layer model can be found in the vein pattern (Fig. 10) observed on the fracture surfaces of metallic glasses. It may be explained as characteristic of the breakup of a fluid layer between two solid surfaces and is similar to the vein pattern obtained by separating two solid surfaces containing a layer of fluid such as vaseline or grease. Questions about the applicability of the fluid layer model arise because the vein pattern is not unique to glassy metals (some crystalline materials also show this pattern, e.g., in shear rupture failure of 18 % Ni maraging steel) [81].

Figure 10. Fracture surface of $Al_{90}Fe_5Ce_5$ metallic glass [3]

4.1.5. Thermomechanical Interaction

The ductility of some amorphous alloys, (e.g., Fe, Co, Mn, and Cr based glasses), is sensitive to thermal treatment. These alloys embrittle upon annealing even though crystallization has not occurred. Figure 11 shows the surface bend strain at fracture in an Fe – Ni – P – B amorphous ribbon as a function of annealing temperature [82]. The annealing-induced embrittlement shows two well-defined stages: Stage I is characterized as fracture following plastic flow, while in Stage II no plastic flow occurs. DAVIS [81] has found that the loss of ductility begins at a temperature lower than that required for initial stress relief of the material.

Embrittlement varies with alloy composition. CHEN et al. [83] investigated the compositional dependence of the embrittlement for Fe – Co and Fe – Ni amorphous alloys. The embrittling temperature is defined as the annealing temperature at which a glass ribbon breaks into pieces when bent over a razor blade. Figure 12 shows the variation of crystallization temperature T_x, and the embrittlement temperature T_B for (Fe, Co)$_{75}$ PBAl and (Fe, Ni)$_{75}$ PBAl glasses with

the Co or Ni content. Mixing Fe, Co, or Ni with one another enhances embrittlement of the alloy glasses, as indicated by the lowering of T_B. This behavior contrasts with the increase in thermal stability of the glassy state, as evidenced by the increase in T_x upon alloying. Increasing the Ni content substantially raises the embrittlement temperature, and replacing Fe and Ni in these glasses with Cr and Mo lowers T_B.

Figure 11. Relationship between surface bend strain at fracture ε_f and annealing temperature in a amorphous $Fe_{40}Ni_{40}P_{14}B_6$ ribbon [87]

So far the mechanisms of thermomechanical interaction are not clear. In some respects metallic glass embrittlement is phenomenologically similar to temper embrittlement of steel. In steels, temper embrittlement is attributed to a strong interaction between impurity and alloying elements which segregate to grain boundaries. In metallic glasses, phosphorus segregation has been observed to cause embrittlement [84]. It is suggested that structural relaxation that leads to local structural and compositional fluctuations may be responsible for the embrittlement of metallic glasses.

4.1.6. Fracture

Tensile specimens of metallic glass ribbon fail by fracture along shear bands oriented at $45 \pm 10°$ to the tensile axis. The fracture surface of the shear band is characterized by a vein pattern and a smooth shear offset region. The smooth region results from initial shear displacement along the shear band. When the shear becomes unstable, fracture occurs and is marked by a vein pattern.

Figure 12. The dependence of embrittlement temperature T_B and crystallization temperature T_x on composition for $(Fe_{1-x}, Co_x)_{75}PBAl$ and $(Fe_{1-x}, Ni_x)_{75}PBAl$ glasses annealed for 20 h [83]

LEAMY et al. [85] first determined that the veins are hills on a flat background and suggested that shear disk cracks nucleate and spread through the shear band. At those places where the cracks run together, the material fails by internal necking, thereby producing smoothly rounded veins. The vein pattern results because of an instability that occurs during the motion of the interface between the fluid and the outside air. In a manner similar to that of dendrite formation during crystal growth, perturbations at the fluid – air interface grow as protrusions into the fluid layer. The protrusions then run into one another on an increasingly larger scale, resulting in the vein pattern. This growth is determined by the balance between the driving force for motion (the negative pressure gradient into the fluid) and an opposing force due to increased surface area (the fluid – air surface tension).

Shear tear tests have been used to determine the fracture toughness K_{IIIC} of metallic glass alloys [86]. In this case, the tearing energy G_t is given by

$$G_t = 2F/t$$

where F is the force required to extend the tear and t the specimen thickness. Therefore,

$$K_{IIIC} = \sqrt{G_t \mu}$$

where μ is the shear modulus.

The fracture toughness of single-edge-notch and center-cracked panels in tensile tests has been evaluated from the following relation [81]:

$$K_C \equiv \sigma_a \sqrt{\pi a}$$

where σ_a is applied tensile stress and a is the crack length.

Figure 13 compares the fracture toughness of metallic glasses with those of crystalline materials. This plot shows that the lower fracture toughness of the iron-based glasses is a natural consequence of their substantially increased yield strengths. On the other hand, the fracture toughness of metallic glasses is ca. 100 times higher than that of oxide glasses.

Considering that most as-quenched amorphous alloys do not form cracks before yielding in bend tests, Kimura and Masumoto [87] developed fracture parameters that describe the ductile behavior of amorphous alloys. These parameters include the plastic constraint factor and the microfactor stress.

The plastic constraint factor L of a double-notched tensile specimen is defined as follows:

$$L = \frac{P_{GY}}{\sigma_Y (W - 2a) t}$$

where P_{GY} is the general yield load, W the specimen width, a the notch depth, and t the specimen thickness. The plastic constraint factor was used to investigate amorphous $Pb_{78}Cu_6Si_{16}N$. A value of 2.4 was found for L, and this value is nearly equal to the upper limit of 2.96 for a deep crack predicted by slip-line field theory. This implies that this alloy is an almost perfectly ductile material.

The microfracture stress σ_f is used to express the fracture criterion for an amorphous, thin bend specimen:

$$\sigma_f = Q\sigma$$

where Q is the plastic concentration factor, and σ the yield stress. The loss of ductility after annealing can be explained as a decrease in the microfracture stress, and not as an inhibition of the slip process.

Figure 13. Fracture toughness of iron-based metallic glass (Metglas) compared to crystalline iron-based metals [81]

4.2. Magnetic Properties

The superior magnetic properties of metallic glasses provide one of the few commercial uses of this class of material [88], [89]. As a result of the random positions of atoms, the ferromagnetic magnetization vector should not have any special anisotropy. That this is not quite true is discussed later; however, this idea led to the strong motivation for the development of soft magnetic materials based on iron, cobalt, and nickel. In this section the soft magnetic properties of amorphous alloys are considered. The term soft refers to the fact that the response of the magnetization to an applied field is large; that is, the material is easily magnetized and demagnetized with low remanent magnetization. This large response of the magnetization coupled with low magnetic losses and low excitation power make amorphous magnetic alloys highly desirable in such applications as transformers and inductors [90]. Further, to be of commercial interest, the material should retain its ferromagnetic properties when heated to elevated temperature. Therefore, the exchange energy that keeps the spins aligned must be fairly large. Even though the coexistence of a long-range ordered ferromagnetic state with a structurally disordered material may, at first, seem surprising, ferromagnetism is usually taken to arise from the nearest neighbor interactions, which in dense random alloys are not very different from those

found in the equivalent crystalline material. This concept of the magnetic properties reflects the short-range order existing in the amorphous alloy, which, in general, mirrors the structure at the same composition in the corresponding crystalline alloys.

Almost all the compositions that produce useful magnetic amorphous structures stable at room temperature contain large fractions of transition-metal or rare-earth elements, many of which are ferromagnetic. More specifically, the class of alloys containing about 80 atom % of the transition metals Fe, Co, and Ni, and about 20 atom % of metalloid or glass-forming elements such as B, C, P, Ge, and Si, are strongly magnetic at room temperature. Since formation of the amorphous state is simpler (that is, lower cooling rates are sufficient) when more than one transition-metal element and metalloid element are employed, many of the available experimental data concern rather complex compositions. The transition metal content can be varied between ca. 75 and 84 atom %, and the alloys of interest magnetically are those containing mainly Fe, Ni, and Co. It is these alloys that offer potential important opportunities for engineering applications.

4.2.1. The Curie Temperature

In ferromagnetism the mutual interactive forces of atomic dipoles tend to align neighboring dipoles to one another, resulting in a permanent magnetic moment on a macroscopic scale. The transition temperature at which thermal agitation perturbs the parallel arrangement of neighboring spins such that the average net moment is zero is the Curie temperature T_C. The Curie temperature of binary iron-nickel, iron-cobalt, and nickel-cobalt alloys with a single metalloid or a combination of metalloid atoms such as B, P, Si, Ge, and C is given in Figure 14 [91]. The Curie temperature of these alloys varies with metalloid concentration in a systematic fashion. The figure can be summarized as follows [91], [92]:

1) T_C decreases with increasing Fe content, which suggests that the structure is behaving more like close-packed, rather than body-centered cubic iron.
2) Substituting Ni for Fe increases T_C only slightly or not at all up to an Fe/Ni ratio of 1 or slightly greater. Further replacement by Ni then decreases T_C in an approximately linear fashion to zero (for pure Ni).
3) The Fe – Co alloys generally show a broad maximum in T_C near a Fe/Co ratio of 1. The addition of Si significantly raises T_C.
4) Replacing Co by Ni results in a rapid drop in T_C in the Co – Ni alloys. Alloys richer than about 85 % Ni are nonmagnetic. Also, in Co – Ni alloys, the Curie point is not sharply defined and the scaling laws are not observed.

Other general observations include:

1) Alloys with one transition metal element have a more sharply defined T_C than alloys containing two or more transition metal elements. This implies that the range in T_C values is a result of chemical inhomogeneity, which may include clustering or phase separation, rather than an intrinsic property of homogeneous amorphous alloys.
2) Alloys rich in P have a tendency for lower values of T_C than alloys high in B, or B plus Si. Also, in the $Fe_x(PB)_y$ alloys, T_C increases as x decreases, which is to say that alloys of higher Fe content have lower Curie temperatures. However this is not always the case for iron only amorphous alloys. It may be that the T_C is sensitive to the Fe – Fe interatomic spacing, which is altered by both the metalloid species and concentration.
3) There is a suggestion [91] that in binary Fe amorphous alloys, the Curie temperature decreases in the order Fe – Si, Fe – B, Fe – C, Fe – P.
4) When other transition metals (i.e., Cr, Mn, Mo, V) are substituted for Fe the Curie temperature is dramatically lowered.

4.2.2. Saturation Magnetization

The saturation magnetization is the maximum magnetic moment (magnetization) per unit volume. The values for saturation magnetization or saturation induction have been reported for a large number of ferromagnetic amorphous alloys, with considerable scatter and disagreement in the results, which can be attributed in part to

the inherent difficulty of accurate magnetization measurements on small samples [91].

The saturation magnetization of binary iron – metalloid alloys varies almost linearly with metalloid content at low temperature [93]. As the temperature is increased above room temperature the saturation magnetization reaches a peak and then drops sharply because T_C is decreasing quickly with increasing metalloid content.

Figure 14. Dependence of Curie temperature on composition in glassy alloys
A) Iron – cobalt – metalloid and nickel – cobalt – metalloid alloys
– – · – $(Fe_xCo_{1-x})_{80}P_{10}B_{10}$; – · – · – $(Fe_xCo_{1-x})_{78}B_{12}Si_{10}$; – · – · $(Fe_xCo_{1-x})_{80}P_{13}C_7$; – – – – $(Ni_xCo_{1-x})_{78}P_{14}B_8$; — $(Ni_xCo_{1-x})_{75}P_{16}B_6Al_3$
B) Iron – nickel – metalloid alloys
– – · $(Fe_xNi_{1-x})_{78}B_{12}Si_{10}$; — $(Fe_xNi_{1-x})_{80}B_{20}$; - - - - $(Fe_xNi_{1-x})_{80}P_{14}B_6$; – · – · $(Fe_xNi_{1-x})P_{13}C_7$

KAZAMA et al., [94] found magnetization to be greatest in Fe_xB_{100-x}. Replacement of B by a different metalloid decreased the magnetization in the order P < C < Si < Ge, as would partially be expected on the basis of the charge transfer model. In similar studies LUBORSKY found P < Si < Ge, C, with the differences between Si, Ge, and C being small [92].

Figure 15. Magnetization (Bohr magnetons per metal atom) as a function of atomic fraction of transition metal
a) $(Fe_xCo_{1-x})P_{10}B_{10}$; b) $(Fe_xNi_{1-x})_{80}P_{10}B_{10}$; c) $(Co_xNi_{2-x})_{78}P_{14}B_8$

Figure 15 illustrates the magnetization in Bohr magnetons for Fe – Ni, Fe – Co, and Co – Ni amorphous alloys [93]. The magnetization is relatively insensitive to the metalloid content; this behavior is similar to crystalline Fe – Ni – Co alloys [95] except that the moments

are higher in the crystalline material (Fe: 2.2 to $2\,\mu_B$, Co: 1.6 to $1\,\mu_B$, Ni: 0.6 to $0\,\mu_B$). This change in the moment per atom in the amorphous state has been interpreted in a rigid-band model [91], in which the moment per metal atom is decreased because of electron contributions to the unfilled d-band by the metalloid elements. [96].

Employing a series of FePB amorphous alloys and altering only the P/B ratio led to the conclusion that boron-containing alloys have a slightly higher moment than those containing only phosphorus [97], [98]. Furthermore, a P/B ratio of 3 : 1 yields a maximum in the moment.

Finally, when transition metals to the left of iron in the periodic table (Mn, V, Cr) are added, a rapid drop in moment follows, with the drop being more rapid for Cr and V than for Mn [91]. The assumption is made that the moments of these atoms (Mn, V, Cr) align antiferromagnetically with the dominant iron moments.

The temperature dependence of magnetization has been measured for a variety of amorphous alloys. The decrease in magnetization with increasing temperature is observed to be more rapid than in crystalline metals. The distribution of atomic spacings which would, in turn, lead to a distribution of exchange interactions can explain this result [91].

4.2.3. Anisotropy

It might be thought that because metallic glasses are amorphous they should exhibit isotropic magnetic properties. They do not because they are not ideally homogeneous alloys, and real glasses have varying degrees of magnetic anisotropy. These result from chemical and structural vagaries which occur during electrodeposition or melt-quenching of the alloys. Stresses resulting from differences in cooling rates through the thickness of the ribbon can also lead to magnetostriction and, therefore, anisotropy. Processing or fabrication of the amorphous alloys contribute to further anisotropic behavior. Thermal annealing can help mitigate the anisotropy through removal of internal stresses.

Magnetostriction is the induced strain inside magnetic domains which results to minimize the elastic strain dependence of the anisotropy energy. Although generally small, it always leads to a contraction in the direction of the field. In spite of the size of the effect it is important in commercial practice because of the possibility of elastic energy being stored by the magnetostrictive force, and even small dimensional changes in laminated ferromagnetic transformer cores can be important. The saturation magnetostriction is expressed by λ_s. Values of magnetostriction in metallic amorphous materials are similar to those in crystalline alloys. Data for Fe – Ni and Fe – Co glasses exhibit nearly a linear decrease in λ_s (Fig. 16) [91]. Cobalt-rich Fe – Co alloys seem to show a negative λ_s. Due to the techniques used to obtain data (strain gages and cement employed) these values represent lower limits [92].

4.2.4. Low-Field Properties

In the application of metallic glasses the low-field properties are usually the controlling factors. Ferromagnetic materials subjected to alternating fields, as in transformers, must have a thin hysteresis loop, because of an energy loss per cycle that is determined by the area enclosed by the hysteresis loop. Because amorphous materials do not have grain boundaries or precipitates as pinning sites they have very low coercivity. However, pinning sites still remain and include defect structures in magnetostrictive alloys, structural rearrangements, and surface irregularities [99]. These can lead to varying degrees of coercive fields. To minimize the coercivity, defect structures must be reduced or elimiated. As the reversal of magnetization in amorphous alloys occurs by wall motion, wall pinning controls the coercive field. Herein surface roughness of the amorphous metal ribbons is a major factor contributing to the coercivity.

Amorphous alloys with high saturation magnetization have losses at 60 Hz that are much smaller than the best commercial grain-oriented Fe – 3.2 % Si alloys [100]. It is these low losses that make the application of amorphous metals in magnetic devices so attractive. Again these low losses are due to the lack of wall pinning centers as well as low anisotropy following stress-relief annealing, which reduces short-order and relaxation effects.

Figure 16. Saturation magnetostriction as a function of atomic fraction of transition metal at room temperature a) $(Fe_xNi_{1-x})_{80}B_{20}$; b) $(Fe_xCo_{1-x})_{80}B_{20}$

4.3. Electrical Properties [2], [101]

The electrical resistivity of metallic glasses is relatively high (i.e., $> 1\,\mu\Omega \cdot m$ at room temperature). In addition to the high electrical resistivity, the temperature coefficient is very small (in some cases, it can be zero or negative) and lies in the range of $\pm 10^{-4}\,K^{-1}$. As a result, glassy metals posses a high residual resistivity near 0 K. This in part stems from the random atomic arrangement of the amorphous structure, which effectively scatters conduction electrons. The randomness of the structure, however, limits the phonon contribution to scattering and leads to the small temperature coefficient of resistivity. Figure 17 is a resistivity – temperature curve for an $Fe_{75}P_{15}C_{10}$ glassy alloy [102]. The temperature dependence for the amorphous phase is small until 675 K when the alloy crystallizes. The residual resistivity near 0 K for the amorphous Fe – P – C alloy is ca. 4 times the values of the crystalline phase.

Figure 17. Variation in relative resistivity (ϱ/ϱ_{rm}) with temperature for the $Fe_{75}P_{15}C_{10}$ glass alloy [102]

The electrical resistivity – temperature curve for some amorphous alloys possesses a minimum below which the resistivity increases with decreasing temperature. Compared to crystalline materials, the minimum can occur at a relatively high temperature. In amorphous $Pd_{80}Si_{20}$ containing 7 atom % Cr, the minimum occurs at 500 K, compared to a temperature of 20 K for Au alloys containing small amounts of Fe [101]. Figure 18 shows this effect for a $Pd_{77.5}Si_{16.5}Cu_6$ alloy that contains 700 ppm Fe as an impurity [103]. The resistance minimum occurs at about 14 K. The curve represented by the dashed line shows what happens to the alloy when a magnetic field (0.7 T) is applied. This implies that the increase in resistance is due to magnetic scattering.

Superconducting amorphous metals and alloys have been obtained in thin film form since 1954 by vapor deposition of bismuth and gallium on cryogenic substrates [104]. However, these early films were unstable and they crystallized at temperatures as low as 50 K. New processing techniques have produced superconducting metallic glasses from the liquid state that are stable at room temperature [105]. The superconducting transition temperatures for these alloys lie between 1.5 and 8.7 K. Table 2 contains data

on superconducting amorphous metals and alloys [106]. These values are extremely low in comparison to conventional metal superconductors (ca. 23 K) and the newer high T_c superconducting oxides (> 90 K). One advantage that metallic glasses may have as superconductors is their amorphous structure. A potential problem with crystalline superconductors (e.g., Nb_3Sn) is the decrease in transition temperature (i.e., from 18 K to less than 4 K) when subjected to radiation. A nuclear fusion reactor is one such environment where superconducting materials could possibly be used and the effect of radiation on structure and properties is of critical importance. The progressive degradation in properties of the crystalline alloy stems from the disordering of the lattice due to neutron bombardment. The disordered structure of glassy metals is relatively unaffected by this type of environment [2].

Figure 18. Low temperature resistivity of $Pd_{77.5}Si_{16.5}Cu_6$ wire in applied fields ($B = 0$ and 0.7 T) [103]

4.4. Chemical Properties [107]

Although the amorphous structure in glassy alloys is thermodynamically metastable, these materials are free of the defects usually associated with crystalline materials, such as grain boundaries, dislocations, and stacking faults; that is, they are free of regions of local electrochemical potential difference. Furthermore, solid-state diffusion is suppressed during rapid quenching. Therefore, metallic glasses are free of the second phases, precipitates, and segregates which usually occur during slow cooling or heattreatment associated with the processing of conventional alloys. The amorphous alloys can therefore be regarded as ideally homogeneous materials in a chemical sense with respect to the surface-related characteristics pertaining to corrosion.

Table 2. Superconductivity transition temperature for selected amorphous materials [106]

Material	T_c, K	Preparation method ∗
$Pb_{90}Cu_{10}$	6.5	VQ
$Sn_{90}Cu_{10}$	6.76	VQ
$La_{80}Au_{20}$	3.5	LQ
$Mo_{48}Ru_{32}B_{20}$	6.05	LQ
$Zr_{75}Rh_{25}$	4.55	LQ
$Nb_{60}Rh_{40}$	4.8	LQ
Nb_3Ge	3.6	S

∗ VQ = vapor quenched; LQ = liquid quenched; S = sputtered

Before the advent of glassy metals it was generally felt that the formation of amorphous passive films would enhance corrosion resistance [108]. Amorphous alloys, being noncrystalline, have an added advantage over crystalline materials in that matching of a substrate alloy with a passive film is more easily accomplished with an amorphous material than trying to find two crystalline alloys for which a quasi-perfect epitaxial relationship exists [109]. Thus, high corrosion resistance can be provided by a chemically homogeneous amorphous alloy. What is especially advantageous in glassy metals is the ability to increase the element beneficial in corrosion resistance while maintaining the chemical homogeneity of the alloy.

An amorphous metal – metalloid alloy containing only one metallic component has a lower corrosion resistance than the pure metal. As an example, the corrosion rate for an amorphous iron – metalloid system without a second metallic element is higher than that of crystalline iron [110]. The corrosion rate decreases, however, with the addition of almost all second elements (e.g., Ti, Zr, V, Cr, Mo, W, Co, Ni, etc.) [111]. In particular, the addition of Cr is very effective; passivation occurs spontaneously

in $Fe_{72}Cr_8P_{13}C_7$ in 2 M hydrochloric acid at room temperature [112]. Figure 19 compares current densities for amorphous $Fe_{70}Cr_{10}P_{13}C_7$ and 18 – 8 stainless steel as a function of time in a sulfuric acid solution [113]. The rate of corrosion for the amorphous Fe – Cr – P – C alloy is two orders of magnitude lower than for the stainless steel. These alloys also do not undergo pitting corrosion, even by anodic polarization, up to the transpassive region of chromium. Chromium also improves the corrosion resistance of amorphous cobalt – and nickel – metalloid alloys.

Figure 19. Current densities for amorphous $Fe_{70}Cr_{10}P_{13}C_7$ glass and crystalline 18 – 8 stainless steel as a function of time in 1 M H_2SO_4 + 0.5 M NaCl (300 mV) [113]

Amorphous metal – metal alloys are usually not corrosion resistant. Their corrosion resistance is always lower than that of the crystalline pure metal component with the highest corrosion resistance or the highest passivating ability [114]. Thus, the overall corrosion resistance is determined by the presence of a passivating element (for example, increasing Si content in an Fe – Si metallic glass improves the corrosion resistance due to the passivating ability of silicon) rather than the fact that the alloy is amorphous [115].

5. Uses of Metallic Glasses

5.1. Mechanical Uses

Although they are strong and inherently fracture tough, metallic glasses are rarely used as structural materials due to the shearing instability they manifest and size limitations resulting from their mode of processing, in which at least one dimension of the product must be small enough to obtain extremely high cooling rates. Plastic flow in metallic glasses occurs in the form of localized shear bands. When multiple shear bands are initiated, metallic glasses can exhibit high macroscopic, as well as microscopic, ductility. But in uniaxial tension, tensile failure is coincident with yielding, because of the highly localized shearing and the absence of strain hardening. The discovery of aluminum glasses [3], [4] has greatly increased interest in metallic glasses as structural materials [116]. Their great asset is their strength, which varies from 670 to 1140 MPa. These values are much higher than the best aluminum alloys (300 – 500 MPa) but suffer from the disadvantage of a lower Young's modulus (up to 71 GPa) [3]. These materials, with their low density and high strength, should be useful as reinforcing composites.

Composites containing metallic glasses may offer means to avoid the problems of low macroscopis ductility and toughness. Composite structures can provide an extrinsic mechanical constraint and also allow use of metallic glasses in bulk form. The combination of high strenght and isotropic two-dimensional form gives amorphous metals promise for planar composites. In fact, high-quality plates have been made of 1.5 cm Metglas [117] ribbons in 0 – 90 ° cross ply with an epoxy matrix [118]. These composites revealed a remarkable degree of in-plane isotropy and strength.

In cement reinforcement, amorphous metal ribbon fibers have been shown to attain superior performance [119]. A 2000-fold increase in specific fracture work was obtained with only 1 vol % of fiber. To improve cohesion to the mortar, the surfaces of the Metglas fibers were roughened by sandblasting.

Another commercial application for amorphous metal is brazing foils. Here, the eutectic alloys, based on nickel, nickel – palladium, and copper, are replacing many conventional brazing materials that have high silver and gold contents. High-strength, high-temperature metal joints are often produced by brazing with foils of eutectic compositions which easily flow into the joint at temperatures as low as possible, but still significantly above the service temperature of the joint. The strong and flexible amorphous metal brazing ribbon conforms well to curved surfaces and provides an optimal, controlled gap. An added advantage is that the glasses contain no binder, and are therefore noncontaminating and have a very long shelf life. In addition, the previously used noble-metal-based crystalline foils can be replaced by amorphous compositions of cheaper materials [89].

5.2. Magnetic Uses

Magnetic uses of metallic glasses already provide a commercial market and are the most promising uses of these materials. The primary commercial application of metallic glasses is in transformer cores. There are about 20 000 000 distribution transformers now in service in the United States alone. In 1984 new distribution transformers were sold at the rate of about 1 000 000 per year [120]. Electric power applications is the only major commercial venture for metallic glasses. The hysteresis of magnetic materials results in energy losses when they are used for cores in high-frequency voltage transformers. Metallic glasses are attractive because with amorphous-metal cores, core loss can be reduced by as much as 50 % compared to conventional transformers [120], depending on specific geometry and design as well as pattern of use [124]. In the United States about 2 % (energy costs greater than $ 10^8 per year) of the total electricity generated is lost in the last stage step-down elements in power distribution transformers before the consumers receive the electricity [122], [123]. Here, the use of amorphous alloy cores could significantly cut energy losses. If all distribution transformers in service in the United States were replaced by amorphous metal transformers, the power savings would amount to about 2000 MW per year [120]. The impact would be much less meaningful in Europe due to the difference in the distribution system. The energy loss in the distribution transformer includes both the magnetic loss in the transformer core and the winding loss in the copper windings. The magnetic loss in the amorphous alloy core is much less compared to silicon steel which is conventionally used for transformers. Also attractive is that the melt-quenched alloys are already in thin ribbon form when produced. This not only reduces the eddy current loss, but is less costly to produce than rolling thin crystalline ribbon tapes to similar dimensions. Although the loss is similar to the nonmetallic ferrite cores in the frequency range up to 10^5 – 10^6 Hz, because of their higher saturation induction the amorphous alloys are more attractive in terms of performance per volume [89], [121].

Some other uses include magnetomechanical transducers that utilize the high magnetoelastic coupling and high elastic limit of amorphous alloys. Based upon this, various applications such as displacement or force sensors have been proposed [125]. Magnetoacoustic applications are feasible because the amorphous alloys are atomistically homogeneous; not only do the domain walls easily move, but ultrasonic sound is scattered only slightly [124]. This contrasts with crystalline solids, in which sound is scattered by lattice defects such as grain boundaries and dislocations. Amorphous alloys are an excellent choice for magnetoacoustic applications, such as delay lines, due to strong magnetoelastic coupling and low acoustic attenuation. In recording and memory applications the sputter-deposited rare earth – transition metal (RE – TM) films can have a strong enough magnetic anisotropy with the easy axis perpendicular to the surface of the film. Magnetic bubble domains can therefore be sustained [126]. Recent interest in magnetooptical recording has revived interest in the use of RE – TM films as a mass storage medium.

A fabric woven from tapes has been used for magnetic shielding because it can be cut and bent into shape without degrading its magnetic performance. Also, the combination of high permeability and high yield strength can be utilized in applications requiring a shield that also serves as a spring (e.g., magnetic tape cassettes). Cobalt-based metallic glasses are being applied as magnetic tape recording head materials. These materials are processed (quenched) between twin

rollers to produce 50-µm thick and 15-mm wide amorphous tapes with acceptable smoothness on both sides. The high flux density coupled with excellent wear resistance results in recording heads produced from these tapes which are superior in overall performance to ferrite, permalloy, and Sendust heads. They have been suggested for use in audio, video, computer, and instrumental recording machinery [127].

The high magnetic permeability of the ferromagnetic amorphous metals makes them good generators of harmonics when placed in appropriate a.c. and d.c. fields [124]. This characteristic makes them useful as antitheft tags for protecting store merchandise or if planted in book spines in libraries and bookstores. The usual system consists of field-generating coils placed around a passageway and a detector of high order harmonics. Since amorphous strips have no crystals, bending does not change the magnetic distortion as it does with conventional crystalline materials.

1. Introduction

Originally the term metallic soaps was only used for metal salts of fatty acids of naturally occurring animal fats (mainly tallow and lard) and vegetable fats. Today, metallic soaps are understood to refer to the sparingly soluble or insoluble salts of saturated and unsaturated, straight-chain and branched, aliphatic carboxylic acids with 8 – 22 carbon atoms. Examples are saturated fatty acids like stearic acid (octadecanoic acid), lauric acid (dodecanoic acid), 12-hydroxystearic acid, and mixtures of acids with 8 – 22 carbon atoms; unsaturated fatty acids like oleic acid (*cis*-9-octadecenoic acid) and linoleic acid (9,12-octadecadienoic acid) (→ Fatty Acids); synthetic carboxylic acids like isostearic acid, 2-ethylhexanoic acid (→ Carboxylic Acids, Chap. 10.4.), dimethylhexanoic acids, trimethylhexanoic acids; and mixtures of synthetic aliphatic isocarboxylic acids.

The salts of the alicyclic naphthenic acids and resin acids (abietic acid) are also frequently regarded as metallic soaps due to properties related to their manufacture and applications. However, the metal salts of resin acids (resinates) no longer have great significance. Naphthenic acids are a byproduct of oil refining (→ Oil Refining). The byproduct is a mixture of linear and cyclic aliphatic hydrocarbons containing carboxylic acid groups.

The production and properties of soaps of almost all metals are described in the literature. However, only the metallic soaps of the following metals (arranged according to the periodic table) are industrially important: lithium, potassium, sodium (group 1); magnesium, calcium, barium (group 2); zirconium (group 4); manganese (group 7); iron (group 8); cobalt (group 9); nickel (group 10); copper (group 11); zinc, cadmium (group 12); aluminum (group 13); lead (group 14); as well as cerium and mixtures of rare earths.

Uses. Metallic soaps are used as thickeners for oils and other organic media, as lubricants (→ Lubricants and Related Products, Chap. 9.) and release agents, as well as drying agents (dryers). Dryers are metallic soaps that accelerate drying as, for example, in the film formation of paints based on drying oils and alkyd resins → Paints and Coatings). Metallic soaps are used

10.1002/14356007.a16_361

as acid scavenger and lubricants both internally and externally in polyolefins and PVC. Sodium and magnesium soaps are important as additives in the pharmaceutical and cosmetics industries, as well as in the building industry. Lithium soaps are especially important as components of lubricating greases.

Properties. The physicochemical properties of metallic soaps are determined by the nature of the metal ion and the organic acid. The metallic soaps of saturated straight-chain carboxylic acids are solids and either have a sharp melting point or melting range, or carbonize on heating without melting. Pastelike products contain water.

Unsaturated fatty acids and branched synthetic acids form metallic soaps with plastic properties. They are therefore usually produced and used in solution.

Types. Metals can form the following metallic soaps depending on their valence and properties:

Neutral soaps:	$RCOOM^{I}$
	$(RCOO)_2M^{II}$
	$(RCOO)_3M^{III}$
Acid soaps:	$(RCOO)_2M^{II} \cdot RCOOH$
	$(RCOO)_3M^{III} \cdot RCOOH$

Acid soaps contain bound free organic acid that can be removed by extraction.

In *basic soaps* $(RCOO)_2M^{II} \cdot (MO)_x$ ($x = 1$, 2), complexed metal oxides can also be present in the form of metal hydroxides or as mixtures of metal oxides and hydroxides.

Mixed soaps $(RCOO)(R'COO)M^{II}$ consist of mixed crystals or mechanically produced mixtures.

Complex soaps: Lead can form complex basic salts: $(PbO)_x \cdot PbSO_4 \cdot [(RCOO)_2Pb]_y$. Other inorganic anions can also be present instead of sulfate.

Overview. A selection of commercially available metallic soaps and those described in the literature is given in Table 1. The soaps are listed in alphabetical order according to the chemical symbol of the metal. The products selected are representative of other homologous soaps. At least one metallic soap of each type is described in the list of references.

2. Production

2.1. Raw Materials

The organic acids used for the production of metallic soaps are either solid or liquid. They are supplied in sacks, drums, containers, or tank cars. The use of products packed in paper sacks should be minimized because of high handling costs and danger of impurities. Acids purchased in drums and containers should be stored at the recommended temperature to avoid total or partial crystallization. For large-scale production, molten acids are generally supplied in tank cars. A tank farm is required, and the tanks should preferably be made of stainless steel to avoid attack on the tank material and darkening and contamination of the product.

Blanketing with an inert gas (e.g., nitrogen or carbon dioxide) may be necessary to prevent darkening caused by oxidation. Acids such as stearic acid, which are solid at room temperature and are supplied as liquids, must be kept above the melting point, preferably by circulation of warm water to avoid overheating at the wall. Stainless steel and aluminum are used as tank materials.

The acids are best dosed in the liquid state; the accuracy of pumps working by volume dosage is sufficient if temperature and density are taken into consideration. Nowadays, mass flow meters are used with better accuracy.

The melting of solid organic acids in the reaction vessel reduces throughput; a separate melting vessel should therefore be used.

The metal salts, which are usually solids, are supplied in sacks, drums, or containers; they are dosed by means of weighing systems. Because the salts may be very toxic, appropriate measures for personal and environmental protection must be taken.

The majority of metallic soaps marketed are stearates. These are salts of stearin, a mixture of mainly $C_{16}-C_{18}$ fatty acids that can be derived both from animal fats (tallow or lard) or from vegetable oils. Recently, the demand for stearates from vegetable sources has increased, mainly for applications in foods, animal feeds, pharmaceuticals, and cosmetics due to the bovine spongiform encephalopathy (BSE) problem, even though stearin from tallow is largely deactivated during its production.

2.2. Industrial Processes

Because of the great number of possible combinations of metal and acid groups, only general production processes can be described here. Three types of reaction are possible:

1) Double decomposition (precipitation)
2) Direct reaction with metal oxides, metal hydroxides, or metal salts of volatile acids
3) Direct reaction with metals

2.2.1. Double Decomposition

In the first step of the double decomposition (precipitation) process the organic acid is saponified with alkali. In the second step, the resulting alkali soap is precipitated by addition of a solution of a water-soluble metal salt:

$$\mathrm{RCOOH} + 2\,\mathrm{NaOH} \longrightarrow 2\,\mathrm{RCOONa} + 2\,\mathrm{H_2O}$$

$$2\,\mathrm{RCOONa} + \mathrm{Ca^{2+}} \longrightarrow (\mathrm{RCOO})_2\mathrm{Ca} + 2\,\mathrm{Na^{+}}$$

The soap solution can also be added to the metal salt solution, or both solutions can be run simultaneously into a separate precipitation vessel. For sparingly soluble alkali soaps, alkaline solutions are used as the reaction medium. Plastic metallic soaps are precipitated in the presence of a water-immiscible solvent which absorbs the metallic soaps formed.

2.2.2. Direct Reaction with Metal Compounds

The reaction of organic acids with metal oxides, metal hydroxides, or salts of volatile acids, such as carbonates, acetates, or formates can be carried out by the following types of process:

1) Melt process
2) Reaction in the aqueous phase
3) Reaction in solvents or lubricants

Melt Process. In the melt process, metal oxides, metal hydroxides, or metal salts of volatile acids are fed into a stirred melt of the organic acid at elevated temperature. The rate of addition should be adapted to the reaction rate to prevent foaming caused by evaporation of water or volatile acid. With unreactive metal compounds, delays can occur in the initial phase. To initiate the reaction, small quantities of water or, for metal oxides, volatile acids such as acetic acid are often added.

The melt process is suitable for metallic soaps with melting points below 140 °C, which produce relatively nonviscous melts. These are generally metallic soaps with sharp melting ranges such as calcium, magnesium, lead, zinc, or cadmium stearate. Alkaline earth stearates are often used in combination with low-melting metallic soaps (e.g., as PVC stabilizers in the combinations barium – cadmium, barium – zinc, or calcium – lead), a low-melting acidic metallic soap is first produced in the melt; the high-melting soap is then formed in the melt of the low-melting one [24].

Reaction in the Aqueous Phase. In the aqueous-phase reaction, metal oxides or hydroxides react in the presence of catalysts such as amines, sparingly soluble alcohols, or other wetting agents. The processes are applicable only to solid metallic soaps (e.g., barium, magnesium, zinc, lead, and calcium stearates) [17].

Reaction in solvents is preferred if the direct melt process is impossible or gives low-quality products, or if the metallic soaps are to be used in solution. Dryers and liquid PVC stabilizers based on branched-chain aliphatic carboxylic acids and naphthenic acids are mainly produced by this process. The solvent (e.g., solvent naphtha or white spirits) also acts as an entrainer for removing reaction water by azeotropic distillation [25].

For solid metallic soaps the solvent can be replaced by organic compounds such as alkanes or fatty alcohols which are solid at room temperature and cannot be saponified by metal oxides. The reaction medium cannot be removed and remains in the final product, which may, for example, be used as a lubricant for plastics [26]. Lubricating greases provide a further example of a reaction product that remains in the reaction medium (→ Lubricants and Related Products, Chap. 9.).

Continuous Process. Metal oxides are dissolved in aqueous ammonia and converted to basic metal carbonates by passage of gaseous carbon dioxide. The molten fatty acids in aqueous ammonia are converted to saponified emulsions. The two components are continuously mixed in the blade region of a rotor – stator mixer with interlocking radial surfaces. The metallic soaps are produced in pastelike to semidry form; they are removed continuously, dried, and ground [27].

Dust-Free Granules. For many uses, metallic soaps do not have to be in powder form. To prevent explosion and promote better handling and dosage, dust-free granules are preferred. The granules are produced from straight-chain fatty acids (C_8–C_{22}) and metal oxides, hydroxides, or carbonates. Granule formation is controlled by the rate of addition of the metal compound, stirring rate, temperature, and water content of the reaction mixture, which is adjusted to ca. 10 wt %. The reactors are mixers equipped for vacuum drying. In the case of unreactive metal oxides (e.g., zinc oxide), chelating acids like citric, tartaric, or glycolic acid are added as catalysts. Because of the small quantity of water involved and the absence of filtration, drying, and pulverization stages, the process runs very economically by using the heat of reaction [28].

2.2.3. Direct Reaction with Metals

Organic acids are treated with metal granules, powders, or gauze at elevated temperature, usually with a solvent as the reaction medium. Direct reaction with metals is used when it offers economic advantages or allows the replacement of unreactive metal oxides by metals [29].

2.3. Plant Equipment

Direct Reaction in Aqueous Media. Reaction vessels, filtration, and drying equipment are necessary for reaction in aqueous media (the precipitation process).

Stainless steel *reaction vessels* are preferred for the production of alkali soaps. The acids

are saponified at 60 – 90 °C at a dilution of 1 : 5 – 1 : 10 depending on the type.

Metal compounds are dissolved at 40 – 50 °C, depending on their solubility, in stainless steel containers. Tanks for intermediate storage of reaction mixtures are equipped with slow stirrers or recirculation pumps.

In the *filtration* of metallic soaps, the filter cake should be as dry as possible for economic reasons. Nutsche (pan) filters, drum filter presses, and plate filter presses have now been largely replaced by membrane filter presses or continually functioning automatic filters. In the direct reaction in the aqueous phase, the filter water produced is used as circulation water and must be put into intermediate storage.

Belt, drum, and rotary dryers have proved successful as *drying units.* In drying units without integrated pulverization and classifying facilities, pulverization units are necessary.

Melt Process. For direct reaction by the melt process or in lubricants, stainless steel or glass-lined reactors fitted with stirrers, heaters (up to 160 °C), and vapor extractors are used. The melts are then processed into a solid, dust-free form by using flaking equipment, cooling belts, or spraying devices. If desired they can be ground.

Precipitation or Direct Reaction in Solvents. For precipitation in the presence of solvents or direct reaction in solvents, stainless steel or glass-lined steel reactors are used that are fitted with stirrers, heaters (up to 160 °C), vacuum connections, and reflux condensers with water separators. Suitable filter equipment is necessary for filtration of viscous solutions. Reaction with metals is also possible in this type of plant. Finally, the product is ground in various mills to obtain different particle size distributions.

2.4. Storage

The liquid to pastelike, solvent-containing metallic soaps are generally stored in packaging forms ready for sale (e.g., cans, drums, or containers). Bags or big bags are often used for powdered metallic soaps. For storage in large silos, protective measures against fire and explosion are necessary (see Chap. 3).

3. Fire and Explosion Protection

Fire Protection. Metallic soaps are flammable substances that burn with intense smoke production. The resulting oxides are carried into the air and may be toxic (heavy metals). This should be taken into consideration during fire fighting. Foam and carbon dioxide extinguishers are suitable fire-fighting agents.

For metallic soap solutions in organic media, local regulations for the handling and storage of flammable liquids must be observed. Plastic metallic soaps are not readily flammable because of their small surface area. Powdered metal soaps have a relatively large surface area and are flammable. With metallic soaps based on unsaturated fatty acids such as oleic and linoleic acids, self-ignition can occur if the packed products are not cooled sufficiently. Self-ignition is promoted by soaps of heavy metals, which are oxidation catalysts.

Explosion Protection. When organic solvents are used in the production of metallic soaps, plants must be protected against explosion by suitable equipment in compliance with prevailing regulations. Metallic soaps in powder form can, like other organic dusts, cause dust explosions, which are most likely to occur during drying, pulverizing, and storage. To prevent buildup of static charge (ignition source), good grounding (earthing) should be ensured. Formation of sparks by metal particles is difficult to avoid. Magnetic separators do not offer any safety improvements because the metals are either nonmagnetic or coated by the metallic soaps. To avoid serious damage, relevant parts of the plant must be equipped with pressure-release devices. If this precaution is not taken, a pressure wave can lead to severe secondary dust explosions and destruction of the plant.

4. Occupational Health and Environmental Protection

Occupational Health. Soaps of calcium, sodium, magnesium, potassium and zinc are nontoxic substances and do not require particular protective measures. Soaps of heavy metals are toxic substances that can lead to acute

or chronic poisoning. Suitable measures to protect the worker are dust extraction, protective clothing, dust masks (when dust sources cannot be avoided), and regular medical checkups. The MAK and TLV values are given for individual metals (Chap. 5).

Wastewater. The filter water produced in the direct reaction in the aqueous phase is collected and reused as reaction water; complete circulation eliminates wastewater production. In the double decomposition reaction, considerable quantities of neutral salts such as sodium sulfate, sodium chloride, and sodium nitrate are produced, which are difficult or impossible to remove by water treatment. This fact should be given particular consideration in the choice of plant location. Other sources of water pollution are bleeding of the filter presses and excess metal salts used for precipitation. Before wastewater is sent to the water treatment plant, the heavy metals are therefore precipitated by addition of lime and/or passing through CO_2 to give a pH of 8.5 – 9.

Air Pollution. Solvent emissions must be reduced in accordance with local regulations by means of a scrubber or absorption tower. Steam- or water-jet vacuum pumps are often used and entrain small quantities of mostly water-immiscible solvents; oil separators are therefore necessary.

The dryers for powdered metallic soaps may release residual dust-laden or water-vapor-containing air into the surroundings. To purify the air, filtration units with large surface areas are necessary. Automatic dust-measuring instruments built into the exhaust stack switch off the plant if the dust concentration becomes too high (e.g., because of a tear in the filter). The residual emission is discharged into the surroundings via a high exhaust stack. Permitted emission values are stipulated in national air purity regulations.

5. Individual Metallic Soaps

5.1. Sodium Soaps

Production. The sodium soaps of stearic and oleic acid have the most industrial importance. They are produced by direct reaction. A solution of sodium hydroxide is added to the fatty acid, and when the reaction is complete, the product is dried and grounded.

Properties. See Table 2.

Uses. Sodium stearate is used in various fields, but mainly in the pharmaceutical and cosmetics industries as an emulsifying and gelling agent. Sodium oleate is largely used in the building industry as an initial dispersing agent that becomes a waterproofing agent after application.

5.2. Potassium Soaps

Producton. The potassium soaps are produced by direct reaction. A solution of potassium hydroxide is added into the fatty acid, and after completion of the reaction the product is dried and ground.

Properties. See Table 2.

Uses. Potassium soaps, mainly stearate and oleate, are used for their swelling properties. They are used to thicken natural and synthetic oils and to raise the melting point and flexibility of waxes and paraffins.

5.3. Lithium Soaps

Production. The lithium soaps of stearic and 12-hydroxystearic acid have the most industrial importance. They are produced by direct reaction in aqueous medium. A very dilute solution of lithium hydroxide hydrate, $LiOH \cdot H_2O$ (concentration ca. 1 : 40, i.e., 2.5 wt %), is slowly added with intense stirring to the fatty acid dispersed in water in the ratio 1 : 20 at 90 °C. Lithium soaps are difficult to filter; flocculation is therefore improved by using an excess of lithium hydroxide or by adding neutral salts. The resulting lithium soap dispersion is, however, often not filtered but spray-dried, even though this involves evaporation of a large quantity of water. Under modified reaction conditions, lithium hydroxide hydrate can be replaced by lithium carbonate and ammonia.

Table 2. Technical data for some commercial soaps of sodium, potassium, lithium, and magnesium

Compound	CAS registry no.	Appearance	Free fatty acid∗, wt %	Total ash or metal content, wt %	Moisture∗, wt %	Bulk density∗, g/L	Melting range, °C
Lithium stearate	[*4485-12-5*]	white powder	1	2.4 Li	0.5	230	190 – 210
Lithium 12-hydroxy-stearate	[*7620-77-1*]	white powder	1	2.3 Li	0.5	400	> 200
Magnesium stearate, technical	[*557-04-0*]	white powder	2	7 – 8	4 – 5	250	115 – 135
Magnesium behenate	[*43168-33-8*]	white powder	2	6 – 7	6.0	250	ca. 140
Sodium oleate	[*143-19-1*]	yellowish powder	0.1	22 – 24	4	350	200 – 210
Sodium stearate	[*822-16-2*]	white powder	1	22 – 24	2	250	210 – 220
Potassium stearate	[*593-29-3*]	white powder	2	12 K	1.5	300	215 min.

∗ Approximate values.

Properties. See Table 2.

Uses. Lithium soaps have particularly good swelling properties. Lithium stearate is used to thicken natural and synthetic oils; to raise the melting point and flexibility of microcrystalline waxes and paraffins; as an additive for coating waxes to increase water repellence; and as a lubricant in the production of injection-molded articles from light metal. Multipurpose lubricating greases have particularly good penetration properties, high oxidation stability, and dropping points up to ca. 200 °C. Lithium 12-hydroxystearate is used primarily for the production of lubricating greases based on synthetic oils (e.g., from silicon and ester oils). These lubricants cannot be produced by the usual saponification in mineral oil because the synthetic oils are attacked under the saponification conditions employed.

5.4. Magnesium Soaps

Magnesium soaps are produced as neutral salts by the double decomposition process, using water-soluble magnesium salts (primarily magnesium chloride) and alkali salts of organic acids in an aqueous medium, or by direct reaction with magnesium oxide. Magnesium soaps in powder form based on stearic acid are particularly important. The degree of purity required, especially with regard to heavy-metal impurities, determines the choice of raw materials in pharmaceutical products. Pharmaceutical quality must fulfill the requirements of the European, Japanese, and U.S. pharmacopoeias.

Properties. See Table 2. Magnesium soaps of long-chain fatty acids have a high specific surface area and can absorb considerable quantities of liquid, giving a creamy consistency. They are insoluble in alcohols, esters, ketones, ethers, and hydrocarbons.

Uses. Magnesium soaps are used in the plastics industry as lubricants and mold-release agents for thermosetting plastics and thermoplastics; in the pharmaceutical industry as processing aids in the production of dragées and as lubricants for tablet pressing; in the cosmetics industry as powder components and for consistency in water-free ointments; in the wax industry to increase the retention of creams based on semisolid wax products and in the production of lubricating waxes; and as a waterproofing agent for the building industry.

5.5. Calcium Soaps

Calcium soaps are generally neutral salts. They are obtained by double decomposition or direct reaction. The raw materials consist of saturated straight-chain aliphatic acids ($C_8 - C_{22}$), montan wax acids, unsaturated straight-chain carboxylic acids (e.g., oleic and linoleic acids), branched-chain aliphatic carboxylic acids (e.g., ethylhexanoic acids), naphthenic acids, and resin acids. Calcium chloride and calcium hydroxide are used as the metal compounds.

Very finely divided calcium soaps of the aliphatic straight-chain carboxylic acids are produced by double decomposition in aqueous

medium. Stearates, myristates, and laurates are commercial products, but the most important calcium soaps are stearates.

Direct reaction 2.2.2 (Melt process) is the most common production method for solid calcium soaps.

In both cases the products are free of water-soluble salts; their purity depends on the quality of calcium hydroxide used.

Calcium soaps are also produced as neutral soaps by the double decomposition process from water-soluble calcium salts and sodium soaps in an aqueous medium. This process can be used to obtain a very high specific surface area, but is mainly used to produce highly crystalline calcium soaps.

Aqueous calcium stearate pastes with a solid content of 40 – 50 % are also produced by the direct process and are used as additives for paper coating (slips).

Calcium soaps which are not in powder form and are therefore used mostly as solutions in organic media (e.g., 2-ethylhexanoates and naphthenates) are produced by direct reaction in an appropriate medium.

Properties. See Table 3.

Uses. Calcium stearate is the most important calcium soap. Calcium stearate is widely used in polyolefins (PE, PP) and in PVC as a lubricant (internal or external), release agent, and acid scavenger. Calcium soaps are used as physiologically inert lubricants and secondary stabilizers in the plastics industry to improve the flow properties and prevent the caking of hygroscopic substances; as lubricants and mold-release agents along with magnesium soaps in pharmaceutical tablet pressing; as waterproofing additives in agents used for building protection and for surface treatment of fillers; and in the paper industry in recording paper, diagram paper, and coating slips.

5.6. Barium Soaps

The most important organic acids in barium soaps are 12-hydroxystearic, lauric, 2-ethylhexanoic, and naphthenic acids. The metal compounds used are barium chloride and barium hydroxide (mono- or octahydrate). The TLV – TWA value for barium is 0.5 mg/m^3.

Properties. See Table 3.

Uses. Barium soaps are used in the paint industry for wetting pigments and as dispersion agents; in metal forming as a component of wire-drawing and other auxiliaries; and in the plastics industry as lubricants and costabilizers.

5.7. Aluminum Soaps

Commercial aluminum soaps are generally produced by treating alkali soaps with water-soluble aluminum salts. In precipitation in aqueous systems, agglomerates of aluminum hydroxide and carboxylic acids are first produced which then react with each other to form salts during the subsequent drying process.

Because aluminum is trivalent, three types of soap are possible:

1) Aluminum monosoaps $Al(OH)_2(OOC{-}R)$
2) Aluminum disoaps $Al(OH)\,(OOCR)_2$
3) Aluminum trisoaps $Al(OOCR)_3$

The polymeric structure of aluminum soaps is not conveyed by the formulas [30].

All types of organic acids are used for aluminum soaps, but particularly stearic, oleic, naphthenic, and 2-ethylhexanoic acids. Aluminum sulfate is preferred as the water-soluble aluminum salt, along with potassium aluminum sulfate and aluminum chloride. In industrial production of the three types of aluminum soap, the organic acids are saponified with 1, 2, or 3 mol of alkali, respectively. Because the three types differ greatly in their thickening properties, commercial products are available with intermediate metal contents. The metal, ash, and free fatty acid contents are given to characterize the soaps.

To achieve special thickening properties, above all for the production of lubricating greases based on mineral oil, fatty acids are combined with aromatic acids (e.g., benzoic or phthalic acid) or with dimeric fatty acids. Lubricating grease with high fastness to fulling resistance and a high dropping point is obtained in this way.

Aluminum soaps in powder form are obtained by double decomposition in aqueous medium.

Table 3. Technical data for some commercial soaps of calcium and barium

Compound	CAS registry no.	Appearance	Free fatty acid∗, wt %	Total ash, wt %	Moisture∗, wt %	Bulk density, g/L	Melting range, °C
Calcium stearate, precipitated	[*1592-23-0*]	white powder	1 – 2	9 – 10	2 – 3	120 – 130	120 – 160
Calcium stearate, direct reaction	[*1592-23-0*]	white powder	0.5	9 – 10	2	200	120 – 160
Calcium arachidate	[*22302-43-8*]	white powder	1	8 – 9	1.5	200 (tapped)	ca. 150

Barium naphthenate	[*61789-67-1*]	dark paste		24 – 25	2		

∗ Approximate values.

Catalyzed reactions between fatty acids and freshly precipitated aluminum oxide hydrate are known but not used industrially. Aluminum oxide hydrate ages too quickly and is not suitable for melting or direct reaction processes in nonaqueous media because of its low reactivity. An exception is the in situ production of lubricating greases in which aluminum alkoxides and freshly precipitated aluminum hydroxide hydrate are used. The TLV – TWA value for aluminum is 10 mg/m^3 for metal dust and 5 mg/m^3 for pyro powders and welding fumes.

Properties. See Table 4. Aluminum soaps of long-chain fatty acids are insoluble in water, lower alcohols, esters, and ketones; they are soluble in hydrocarbons, toluene, xylene, ethylene glycol, chlorinated hydrocarbons, and vegetable and mineral oils. The most striking property of aluminum soaps is their capacity for thickening organic media and for forming solid gels with them. Gel consistency increases in the order trisoaps, disoaps, and monosoaps. The gels are destroyed by polar substances such as primary amines, ammonia, pyridine, and lower alcohols.

Uses. The gel-forming property of aluminum soaps is exploited in the mineral oil, cosmetics, and pharmaceutical industries. They are also employed in the paint industry as antisettling and matting agents and for wetting pigments. Aluminum soaps in powder form are used as lubricants in thermosetting plastics and thermoplastics, as waterproofing agents in building protection, and as flow promoters for caking powders.

5.8. Lead Soaps

Neutral lead soaps are produced by double decomposition, by direct reaction in the melt, or by direct reaction in aqueous media in the presence of catalysts such as triethanolamine and sparingly soluble alcohols [17].

Basic lead soaps are produced by direct reaction in the presence of catalysts in aqueous media. The addition salts contain a maximum of two molecules of lead(II) oxide to one molecule of neutral lead soap:

$$3\,PbO + 2\,HOOCR \rightarrow 2\,PbO \cdot Pb(OOCR)_2 + H_2O$$

Direct reaction in the melt does not go beyond the addition of one molecule of lead(II) oxide because of an increase in the melting point. In the presence of a fusible organic medium

Table 4. Technical data for some commercial aluminum soaps

Compound	CAS registry no.	Appearance	Free fatty acid∗, wt %	Total ash, wt %	Moisture∗, wt %	Tapped bulk density, g/L	Melting range, °C
Aluminum tristearate	[*637-12-7*]	white powder	16 – 22	7 – 8	1.2	300	110 – 130
Aluminum distearate	[*300-92-5*]	fine white powder	3 – 7	10 – 11	1.2	82	150 – 160
Aluminum monostearate	[*7047-84-9*]	white powder	1 – 3	13 – 14	1.2	170	180 – 250
Aluminum di-12-oxystearate	[*7047-84-9*]	fine white powder	4 – 6	7.5 – 8.5	1.5	110	ca. 140
Aluminum dipalmitate	[*14236-50-1*]	fine white powder	5 – 7	10.5 – 11.5	1	300	ca. 160
Aluminum monopalmitate	[*555-35-1*]	very fine white powder	2 – 4	15.5 – 16.5	1.5	280	ca. 200
Aluminum dimyristate	[*56639-51-1*]	fine white powder	6 – 9	10.5 – 11.5	1	300	ca. 145
Aluminum dilaurate	[*817-83-4*]	white powder	4 – 6	10.5 – 11.5	1	280	ca. 150

∗ Approximate values.

(e.g., $C_{16}-C_{18}$ fatty alcohols, or a combination of fatty alcohols and paraffin or long-chain fatty acid esters), however, a further molecule of lead(II) oxide can be added to give dispersions of dibasic lead soaps [24]. The basicity of basic lead soaps in the direct reaction in solvents depends on their solubility. In general, only one molecule of lead(II) oxide can be added.

Basic Lead Complex Soaps. The starting material for basic lead complex soaps is an aqueous dispersion of a basic inorganic lead salt which reacts with fatty acids in the presence of catalysts in an aqueous medium [31]:

$$4\,PbO \cdot PbSO_4 + 2\,HOOCR \rightarrow$$
$$3\,PbO \cdot PbSO_4 \cdot Pb(OOCR)_2 + H_2O$$

Production. Technical-grade stearic, oleic, 2-ethylhexanoic, and naphthenic acids are used for the production of the most important lead soaps. The principal metal source is lead oxide. Lead acetate is used as the water-soluble lead salt in the double decomposition process. Direct reaction in aqueous medium is performed with reactive lead(II) oxide (litharge, commercial specification "canary yellow"). The red lead oxide content should be very low because this modification cannot form basic addition salts. The red modification is, however, suitable for the production of neutral salts in the melt or in an aqueous medium. In the melt process, the lead metal content of the lead oxide should be very low to avoid blockage of valves by agglomeration.

Regulations for personal and environmental protection must be observed, particularly with lead soaps in powder form. Even the absorption of small quantities of lead can lead to chronic illness (→ Lead, Chap. 9.; → Lead, Chap. 10.). The MAK value for lead is 0.1 mg/m^3 and the TLV – TWA value is 0.15 mg/m^3.

Properties. See Table 5.

Uses. Neutral and basic lead stearates are used as heat stabilizers and lubricants in PVC processing; as lubricants in the pencil industry; and as additives for specialty papers. Lead 2-ethylhexanoate, naphthenates, and resinates are used in the paint industry for wetting pigments and as dryers, and in the mineral oil industry as components of high-pressure lubricants.

5.9. Copper Soaps

Copper forms neutral soaps which are produced either by double decomposition or by the direct process in the melt or in organic media. Production from metallic copper is also known: copper powder is dispersed in solvent naphtha; copper soaps that are soluble in solvent naphtha are formed by passage of air in the presence of an organic acid.

Table 5. Technical data for some commercial soaps of lead and copper

Compound	CAS registry no.	Appearance	Free fatty acid∗, wt %	Total ash or metal content, wt %	Moisture∗, wt %	Bulk density, g/L	Melting range, °C
Neutral lead stearate	[*1072-35-1*]	white powder	1	27 – 28 Pb	0.2	500	105 – 110
Monobasic lead stearate	[*90459-52-2*]	white powder	1	41 – 42 Pb	1	250 – 300	110 – 120
Dibasic lead stearate	[*56189-09-4*]	white powder	1	51 – 52 Pb	0.5	450	> 200 (decomp.)
Lead 2-ethylhexanoate	[*16996-40-0*]	white, plastic	1	ca. 45	0.5		
Lead oleate	[*1120-46-3*]	brown mass	1	30 – 31	1		ca. 65
Lead naphthenate	[*61790-14-5*]	dark, viscous mass	1	30 – 31	1		
Copper stearate	[*7617-31-4*]	blue-green powder	1	14 – 15	1		ca. 155
Copper laurate	[*19179-44-3*]	blue-green powder	2	17 – 18	1		ca. 125
Copper 2-ethylhexanoate	[*22221-10-9*]	blue mass		23 – 24	1		
Copper oleate	[*10402-16-1*]	blue-green mass		13 – 14	1		
Copper naphthenate	[*1338-02-9*]	gray-green paste		14 – 15	1		

∗ Approximate values.

Commercial copper soaps are produced from stearic, naphthenic, oleic, and 2-ethylhexanoic acids. Water-soluble copper salts, mainly copper sulfate, are used as copper source for the double decomposition; copper hydroxide or basic copper carbonate is used for direct reaction.

Production of copper soaps in powder form by double decomposition requires a separate plant, because cleaning the drying and filtration units is almost impossible. The MAK values for copper are 0.1 mg/m^3 (fume) and 1 mg/m^3 (dust); the TLV – TWA values are 0.2 mg/m^3 (fume) and 1 mg/m^3 (dusts and mists).

Properties. See Table 5.

Uses. Copper soaps are used mainly as fungicides in wood and ship paints, textiles (e.g., tents, awnings, sandbags, camouflage netting, ropes), paper, and cardboard. Compared with inorganic copper compounds, they have the advantage of being difficult to wash out. Naphthenates, oleates, and 2-ethylhexanoate are used as solutions in organic media.

5.10. Zinc Soaps

The most important zinc soaps are the zinc stearates.

Neutral zinc soaps are produced by double decomposition, direct reaction in the melt, direct reaction in aqueous or organic media, and reaction of zinc oxide with fatty acids below the melting point of the soaps.

Basic zinc soaps produced by double decomposition are obtained in powder form; the basic moiety can be in the form of a basic soap, zinc oxide, or zinc carbonate. In organic media, soluble zinc soaps (particularly naphthenates, 2-ethylhexanoate, and oleates) can be rendered basic during the direct reaction by addition of excess zinc hydroxide. Soaps with 1.7 equivalents of zinc hydroxide to 1 equivalent of acid can be obtained.

Commercial zinc soaps are produced from stearic, lauric, oleic, 2-ethylhexanoic, and naphthenic acids. Those derived from stearic acid are produced on the largest scale. Water-soluble salts, preferably zinc sulfate and chloride, are used as zinc source for double decomposition; zinc oxide, hydroxide, carbonate, and acetate are employed for direct reaction. When several types of product are prepared in a single plant, attention must be paid to the production order because zinc stearate acts as a gel breaker with gels from aluminum soaps. Normally calcium, magnesium, zinc, and aluminum soaps are produced in a single plant.

Properties. See Table 6.

Uses. Zinc soaps are used for the following purposes:

1) In the plastics industry as lubricants, release agents, and components of PVC stabilizers

Table 6. Technical data for some commercial soaps of cadmium and zinc

Compound	CAS registry no.	Appearance	Free fatty acid∗, wt %	Total ash, wt %	Moisture∗, wt %	Bulk density, g/L	Melting range, °C
Cadmium stearate	[*2223-93-0*]	white powder	2	19 – 20	1	180	105 – 115
Cadmium 12-hydroxy-stearate	[*69121-20-6*]	white powder	2	18 – 19	1	220	110 – 118

Cadmium oleate	[*10468-30-1*]	brown mass		19 – 20	2		
Cadmium 2-ethyl-hexanoate	[*2420-98-6*]	yellowish paste		32 – 33	2		
Zinc stearate, precipitated	[*557-05-1*]	white powder	0.5	13 – 14	1	140	118 – 122
Basic zinc stearate, direct reaction	[*557-05-1*]	white powder	0.5	15 – 17	1	300	118 – 122
Zinc stearate, direct reaction	[*557-05-1*]	white powder	0.5	13 – 14	1	300	118 – 122
Zinc 12-hydroxystearate	[*35674-68-1*]	white powder	1	12.5 – 13.5	1	220	145 – 155
Zinc laurate	[*2452-01-9*]	white powder	1	17 – 18	1	220	122 – 126
Zinc arachidate	[*22302-43-8*]	white powder	1.5	12 – 13	1	180	120 – 124
Zinc oleate	[*557-07-3*]	bright mass		13 – 14	0.3		
Zinc 2-ethylhexanoate	[*136-53-8*]	clear, highly viscous liquid		23 – 24	1		
Zinc naphthenate	[*12001-85-3*]	brown mass		14 – 15	0.4		

∗ Approximate values.

2) In the rubber industry, as release agents for unvulcanized products (wettable zinc stearate soaps and zinc stearate dispersions in water are also used)
3) In paints, as matting agents and abrasives
4) In building protection, as waterproofing agents
5) For textiles, also as waterproofing agents
6) In the cosmetics and pharmaceutical industries, as additives to body and face powders
7) As components of wire-drawing greases (special zinc arachidate is used in tube drawing because of its low ash content)
8) In paints, as components of dryers and as anticaking agents for powdered products

5.11. Cadmium Soaps

Neutral and basic cadmium soaps are produced by double decomposition, direct reaction in the melt, or direct reaction in organic media. Stearic, lauric, 12-hydroxystearic, oleic, and 2-ethylhexanoic acids are commonly used. Cadmium sulfate, chloride, and nitrate are used in double decomposition; cadmium oxide and hydroxide in the direct reaction. Cadmium soaps are highly toxic. Cadmium accumulates in organs such as the liver and adrenal gland and is released very slowly. Absorption of very small quantities of cadmium over a long period therefore leads to chronic illness. The TLV – TWA value is 0.05 mg/m^3.

Properties. See Table 6.

Uses. The use of cadmium soaps as components of PVC stabilizers is decreasing because of their toxic properties. Solid PVC stabilizers contain cadmium soaps of saturated fatty acids, whereas liquid stabilizers contain soaps of unsaturated or branched, short-chain fatty acids. The soaps act as heat and light stabilizers, and soaps of saturated fatty acids are used as lubricants in the processing of PVC. Unlike other metallic soaps used in the PVC sector, cadmium soaps do not affect transparency and are suitable for hard, transparent PVC products.

5.12. Manganese Soaps

Neutral manganese(II) soaps are produced by double decomposition from alkali soaps and water-soluble manganese salts in an aqueous medium or in the presence of organic solvents, and by direct reaction in the melt or in organic media with manganese oxides, hydroxides, or salts of volatile acids. The oxides and hydroxides are very unreactive and must be freshly prepared; conversion is generally incomplete. In

the reaction with metallic manganese in powder form or as divided gauze, lower carboxylic acids (e.g., acetic acid) are added to the solvent as catalysts.

Basic manganese(II) soaps are produced by double decomposition in an aqueous medium; oversaponified alkali soaps (i.e., more than 1 mol of alkali is used per mole of acid) react with water-soluble manganese salts. The excess alkali forms manganese hydroxide or manganese oxide hydrate, which adds to the neutral manganese soap. Whether a true addition salt or a simple mixture is formed is unclear. The basic manganese soaps are insoluble or sparingly soluble in organic solvents. Stearic, oleic, naphthenic, and 2-ethylhexanoic acids are commonly used. Sources of manganese for the double decomposition are water-soluble manganese salts such as manganese chloride and sulfate; for the direct reaction, manganese oxide, hydroxide, and acetate.

Manganese soaps are hazardous to health. A particular danger arises from dust formation by products in powder form. Because of their brown color, separate production plants are necessary for the powdered products. The TLV – TWA values for manganese are 5 mg/m^3 (dust) and 1 mg/m^3 (fume).

Properties. See Table 7.

Uses. Manganese soaps are used mainly as dryers in paints, printing inks, and varnishes based on drying oils or alkyd resins. Basic powdered products are also added to printing inks.

Manganese soaps can be used as catalysts (e.g., in paraffin oxidation or the reduction of fatty acids to alcohols).

5.13. Iron Soaps

Only neutral iron(III) soaps are produced industrially. Formation of basic soaps by addition of iron oxide or hydroxide is known but is not exploited commercially.

Iron soaps are obtained by double decomposition from alkali soaps and water-soluble iron salts in an aqueous medium with or without organic solvents. Direct reaction in the melt with iron oxides does not go to completion and is very slow; the unreacted free fatty acid is extracted with alcohol.

Raw materials used are stearic, oleic, naphthenic, and 2-ethylhexanoic acids. In double decomposition, iron(III) chloride is generally used as the iron source; in the direct reaction, iron oxide, hydroxide, or carbonate are used. Because of the intense color of iron soaps, separate precipitation units are necessary. Although iron soaps do not pose a danger to health, local regulations regarding personal and environmental protection for dust-producing products must be observed during handling.

Properties. See Table 7.

Uses. Iron soaps are components of dryer mixtures. Because of their intense color, they are used only with dark colors. The function of the iron as a dryer is based on polymerization at elevated temperature rather than catalysis of oxidation.

Further uses are as hydrogenation catalysts, as dry-film lubricants in the form of monomolecular adhesive layers, in the production of fast-copy paper, in waterproofing, and in pharmaceuticals as oil-soluble iron compounds for the treatment of anemia.

5.14. Cobalt Soaps

Neutral and weakly basic cobalt(II) soaps are known. They are produced by double decomposition using alkali soaps with water-soluble cobalt salts in an aqueous medium with or without organic solvents, or by direct reaction via the melt process, or in solvents. Reaction of metallic cobalt in powder or gauze form in organic media is also possible; air acts as an oxidizing agent.

Stearic, oleic, naphthenic, and 2-ethylhexanoic acids are used. For double decomposition, cobalt(II) sulfate is used as the water-soluble salt; for the direct reaction, cobalt acetate, cobalt(II) hydroxide, and cobalt(II) oxide are used.

Cobalt soaps have an intense blue-violet color. Soaps in powdered form must be produced in separate plants. Dust from cobalt soaps is hazardous to health. Local regulations concerning personal and environmental protection and the compulsory labeling of packaging must

Table 7. Technical data for some commercial soaps of iron, cobalt, nickel, and manganese

Compound	CAS registry no.	Appearance	Free fatty acid∗, wt %	Total ash or metal content, wt %	Moisture∗, wt %	Melting range, °C
Iron(III) stearate	[*555-36-2*]	red-yellow powder	5	14 – 15	1	ca. 90
Iron oleate	[*23335-74-2*]	red paste		9 – 10	2	
Iron 2-ethylhexanoate	[*6535-20-2*]	reddish paste		16 – 17	1	
Cobalt stearate	[*13586-84-0*]	blue – violet powder	1	13 – 14	1	ca. 150
Cobalt 2-ethylhexanoate	[*136-52-7*]	blue – violet mass		22 – 23	1	
Cobalt naphthenate	[*61789-51-3*]	dark blue mass		10 – 11 Co		
Nickel stearate	[*2223-95-2*]	bright green powder	1	14.5 – 15.5	1	80 – 86
Nickel oleate	[*13001-15-5*]	greenish paste	1	22 – 23	1	
Nickel 2-ethylhexanoate	[*4995-91-9*]	green paste		22 – 23	1	
Nickel naphthenate	[*61788-71-4*]	deep green mass	1	8.5 – 11.5 Ni	1	
Manganese stearate	[*3353-05-7*]	bright brown powder		13 – 14	1	ca. 80
Manganese(II) oleate	[*23250-73-9*]	brown mass		12 – 13	1	
Manganese 2-ethylhexanoate	[*15956-58-8*]	brown mass		ca. 16 Mn		
Manganese naphthenate	[*1336-93-2*]	dark brown mass		ca. 10 Mn	1	

∗ Approximate values.

be observed. The TLV – TWA value for cobalt is 0.05 mg/m^3.

Properties. See Table 7.

Uses. Cobalt soaps are very effective dryers for printing and writing inks because they catalyze oxidation. Cobalt stearate is used as an adhesive for rubber – metal bonding.

5.15. Nickel Soaps

Divalent nickel forms neutral to weakly basic soaps. They are produced by double decomposition from alkali soaps and water-soluble nickel salts in an aqueous medium in the presence of organic solvents or by direct reaction in the melt or in solvents with nickel oxide, hydroxide, or salts of volatile acids. In the melt process, decomposition occurs above 200 °C with formation of a black powder. The usual acids are stearic, oleic, 2-ethylhexanoic, and naphthenic acids. Nickel sulfate and chloride are used as water-soluble salts for double decomposition, and nickel(II) hydroxide, oxide, acetate, or carbonate for the melt process.

Nickel soaps in powder form must be produced in separate plants because of their intense green color. Dust from nickel soaps is hazardous to health. Local regulations concerning personal and environmental protection and compulsory labeling must be observed. In processing nickel oxide and carbonate, protective measures must be taken because of their carcinogenic properties. The TLV – TWA value for nickel is 1 mg/m^3.

Properties. See Table 7.

Uses. Nickel soaps are used as oxidation catalysts in dryers; as oil-soluble hydrogenation catalysts, which liberate finely divided nickel on heating or decomposition; as detergents in petroleum ether; and as additives in lubricating oils for preventing cyclization and resinification.

6. Quality Specifications

Metallic soaps can be characterized by a series of data. Certain application-orientated properties, such as solubility and swelling, may have

to be determined in special tests on test formulations.

Solid Metallic Soaps. The following parameters are determined:

Moisture Content. The sample is weighed before and after heating at 110 °C for 2 h in a drying oven.

Metal Content. Metal content is determined by one of the usual analytical methods after acid decomposition of the metallic soap in an aqueous extract.

Total Ash. The substance is preheated carefully in an incinerator and then heated slowly to 800 – 1000 °C in a muffle furnace as soon as all the organic substance has decomposed. After being cooled in a desiccator, the ash is determined by back-weighing. For lead soaps, attention must be paid to reduction to metallic lead.

Washed Ash. Residue from the determination of total ash is boiled in distilled water and filtered; the residue and the filter paper are incinerated. The final residue is expressed as a percentage of the weight of substance used for the total ash determination. This method is not applicable to water-soluble metal oxides.

Water-Soluble Salts. The difference between total ash and washed ash is described as soluble ash or water-soluble salt. For metallic soaps produced by double decomposition, this parameter gives a good indication of whether the salts have been washed sufficiently.

Free Fatty Acids. The substance is refluxed with acetone for 10 min and filtered; the fatty acid content is determined by titration with alcoholic potassium hydroxide using thymol blue and cresol red as a mixed indicator.

Particle Size. Particle size is determined as residue on a 71 µm air-stream sieve or by wet sieving of an aqueous dispersion with a surfactant.

Tapped Bulk Density. Tapped bulk density is determined in a commercial tamp volumeter by using a fixed number of impacts.

Bulk Density. The substance is passed through a 500-µm sieve into a measuring cylinder up to the 100-mL mark and weighed.

Melting Range. Melting range can be determined in a commercial melting point apparatus.

pH value. pH determination on the soap dispersion.

Fatty Acids Composition. Fatty acids composition is determined by gas chromatography with direct injection of a methyl esters solution obtained from the soap.

Metallic Soap Solutions. For metallic soap solutions (e.g., used as PVC stabilizers or dryers), metal content, density, viscosity, solid content, and Gardner color index must be determined. Industrial supply conditions are to be observed for metallic soap dryers [32].

7.2. Hydrometallurgical Methods
8. Metal Recycling
9. Fabrication Technology

[Top of Page]

1. Introduction

Metallurgy, as discussed in this article, covers only the field of metal production and refining, starting with the handling of raw materials and ending with refined metals. This definition excludes the topics fabrication technology and properties of metals and alloys (physical metallurgy). The fabrication of metals is mentioned very briefly at the end of this article to place it into perspective with regard to extractive metallurgy as discussed here.

Concentration of minerals, scrap, and intermediate materials is the first major step in metallurgy and involves the size reduction of the aforementioned materials, and separation from the bulk of the gangue material, followed by agglomeration, if necessary. This renders the aforementioned materials into a suitable form for downstream processes.

The subsequent extractive metallurgical processes cover four main areas:

1. Pyrometallurgy: smelting operations at high temperature
2. Hydrometallurgy: aqueous solution operations and electrolysis at low temperature
3. Metal refining
4. Electrometallurgy: electrolysis, smelting, melting, and refining operations at high temperature, and aqueous electrolysis and refining at low temperature

A general flow diagram of metallurgy (Fig. 1) illustrates the interrelationship of these aspects.

Figure 1. General flow sheet of extractive metallurgy

[Top of Page]

2. Raw Materials and Products [10-13]

Without raw materials and energy no extractive metallurgy and hence no products could exist. This chapter presents an overview of all the raw materials (primary or secondary) and energy sources required to produce metallurgical products.

2.1. Energy

Most metallurgical processes require energy for the completion of the following operations: size reduction, heating, reactions, mixing, and phase separation. The required energy may be available in the form of chemical energy, heat from the combustion of fuels, electrical energy, sensible heat, mechanical energy, or buoyancy forces. In many cases an energy source is not used for only one purpose, but for several at the same time. On the other hand several energy sources may be used in one process. Examples of the application of these energy sources are:

1. Melting of metals and alloys in an induction furnace is performed with electrical energy which heats and agitates the melt.
2. During smelting in shaft furnaces, coke has a multitude of functions, e.g., heating, reduction, and mechanical stabilization in the shaft column (⟶ Iron).
3. Oxygen injection in a steel converter (⟶ Steel) is the only energy source for reactions (exothermic oxidation of impurities), mixing (by buoyancy forces of the gas), and heating (via energy released by exothermic oxidation reactions).
4. In Waelz kiln operations heating is done principally by the combustion of hydrocarbons, the intermediate reduction is brought about by the partial burning of added coke, and mixing is effected by the rotation of the furnace.

In some cases these different kinds of energy are interchangeable, in other cases, only one specific type of energy may be applied.

2.2. Ores

Most metals occur in nature in mineral form, although a small number of metals (e.g., Cu, Ag, Au, Hg, Pt) may occur in their metallic state. A mineral can be defined as a homogeneous substance of definite composition and crystal structure. These minerals are found in varying compositions in nature in close association with various gangue materials, this association is called an ore if it can be exploited economically. Another large source of primary minerals are the oceans and salt lakes. Table 1 depicts the usual classification of minerals (with examples) according to their chemical composition.

Table 1. Classification of minerals and examples

Substances	Examples
Elements	Au, Ag, Cu, As, Sb, Bi
Sulfides	CuS, Cu_2S, PbS, ZnS, NiS, Cu_5FeS_4,

	$CuFeS_2$, FeS, FeS_2, MoS_2
Oxides and hydroxides	Fe_2O_3, Fe_3O_4, $FeTiO_3$, $FeCr_2O_4$, TiO_2, MnO_2, SnO_2, Al_2O_3, $Al(OH)_3$, AlOOH, FeOOH
Halides	NaCl, KCl, CaF_2, Na_3AlF_6, $KMgCl_3 \cdot 6\ H_2O$, $Cu_2Cl(OH)_3$
Carbonates, nitrates, and borates	$MgCO_3$, $CaCO_3$, $FeCO_3$, $MnCO_3$, $ZnCO_3$, $CaMg(CO_3)_2$, $Cu_2CO_3(OH)_2$, $NaNO_3$, $Na_2B_4O_7 \cdot 10\ H_2O$
Sulfates, chromates, molybdates, and tungstenates	$BaSO_4$, $PbSO_4$, $CaSO_4$, $CaSO_4 \cdot 2\ H_2O$, $KFe_3(SO_4)_2(OH)_6$, $CaWO_4$, $FeWO_4$
Phosphates, arsenates, and vanadates	$(Ca, Ce, Nd)PO_4$, $(Ce, La, Th)PO_4$
Silicates	$ZrSiO_4$, $ZnSiO_4$, SiO_2, $LiAlSi_2O_6$

In most cases primary ores are further processed close to the mine site to decrease their volume and increase the concentration of valuable mineral(s) therein, before they are shipped or undergo further metallurgical treatment.

Additional materials are required to enhance the extraction of metals from the primary ores and for subsequent refining. These are substances which:

1. produce better phase separation during smelting,
2. serve as solvents for minor components during smelting, and
3. enable selective oxidation or reduction of certain components.

2.3. Intermediate Materials

Ores mostly contain more than one economically valuable mineral. However, the concentration of these valuable minerals may be too low in most cases for direct *pyrometallurgical* recovery, hence they are accumulated in certain *slags* (mixtures of oxides), *mattes* (mixtures of heavy-metal sulfides), *speisses* (mixtures of heavy-metal arsenides and antimonides), *drosses* (mixtures of metals and oxides), *skimmings* (mixtures of metals and oxides), *flue dusts* (mixtures of oxides, chlorides, and sulfates) etc., which are subsequently refined. In *hydrometallurgical* operations these elements accumulate in sludge, leach residue, anodic slime, and cementates. Processing of these materials not only prevents loss of valuable minerals but also minimizes the volume of the wastes and costs of disposal. Table 2 summarizes some intermediate materials.

Table 2. Intermediate materials in metallurgy

Material	Mixture of	Collector for
Pyrometallurgy		
Slags	stable oxides	Zn (Pb)
Mattes	heavy-metal sulfides	Cu, Ni, PM *
Speisses	heavy-metal	
arsenides and antimonides	Cu, Co, Ni, As, Sb, PM *	
Flue dusts	oxides, chlorides,	
and sulfates	Pb, Zn, Cd, Tl	
Drosses	metals and oxides	depends on process
Skimmings	metals, oxides, etc.	depends on process
Hydrometallurgy		
Sludges, leach		
residues	insolubles	Pb, PM *
Anodic slimes		PM *, Pb, As, Sb, Sn, Se, Te
Cementates	metal slimes	Cu, Ni, Co, Cd

* Precious metals.

2.4. Scrap

Scrap is metallic and generally requires only sorting, melting, and refining before products are manufactured. Processing of secondary metals usually requires much less energy than processing of primary materials and, in addition, results in less pollution. Three types of scrap may be distinguished:

1. New scrap (home scrap): generated during the production of metals
2. Prompt scrap: generated in the manufacturing of metal products
3. Old scrap (obsolete scrap): waste products such as used batteries, automobiles, cans

Because of its unknown composition, recycling of obsolete scrap is the only item that presents a problem during refining.

2.5. Products

The final products of hydro- and pyrometallurgical operations appear in various forms, the most common being metal alloys and, in some cases, inorganic compounds of the valuable metals. The characteristics of the product may be defined in terms of the following:

1. chemical state (metal, oxide, salt, etc.),
2. physical state (solid, liquid, bar, rod, powder, solution, etc.), and
3. chemical and physical standards which have to be met (purity, microstructure etc.). A variety of standards for metals and alloys has been established in the international metal industry (e.g., ASTM, SAE, DIN, EN and BS) to facilitate trade. Similar standards for inorganic metal compounds can be found in the different national pharmacopoeias (e.g., B.P., DAB, and U.S.P.). However, the chemical industry relies largely on producer specifications.

[Top of Page]

3. Material Concentration [14-17]

A series of relatively cheap processes, mostly physical, is applied to prepare ore and other raw feed materials for treatment in the various metallurgical processes. In general these processes can be discussed under the following headings:

1. *Size reduction,* during which the valuable minerals in the ore are released and exposed from the surrounding gangue material, or scrap and intermediate materials are rendered suitable as an input to subsequent processes
2. *Particle selection,* which concentrates and, to a large extent, separates valuable minerals or materials from the bulk of the gangue
3. *Agglomeration,* which agglomerates fine materials into larger particles, for use in blast furnaces, for example

The interrelations of these aspects are shown in Figure 2.

Figure 2. Flow sheet of material concentration

3.1. Size Reduction (⟶ Size Reduction)

Size reduction (comminution) is accomplished in a sequence of physical processes, which commence with *crushing* in jaw, gyratory, cone, roller, and fine crushers, and, if possible, in hammer mills. Oversize material is recycled to the appropriate crushing unit in a closed-loop configuration.

Subsequent *milling* is carried out in ball, rod, tube, and pebble mills in a closed-loop configuration. In many modern applications, however, crushing has been replaced by closed-loop autogenous and semiautogenous milling, in which hydrocyclones and other classification equipment are used to produce a suitable particle size distribution. The size reduction of scrap and intermediate material can also be effected by shredders.

3.2. Particle Selection

During sorting, various properties of the particles (e.g., size, density, luminosity, magnetic, electrostatic, and surface properties) may be utilized to separate the valuable mineral or material from the surrounding gangue.

Separation According to Particle Size. The separation of particles according to size is effected by the use of physical barriers and screens (⟶ Screening) or by the differential movement of solid particles through fluids. These operations are performed in, e.g., rake classifiers (⟶ Elutriation), sedimentation classifiers, and hydrocyclones (⟶ Centrifuges, Sedimenting, ⟶ Hydrocyclones).

Separation According to Density. The sorting of particles as a function of their density may be performed in unit operations and devices such as Humphreys Spiral, shaking tables, jigging and tabling operations, as well as dense-medium separations (⟶).

Separation due to Surface Properties. Under certain chemical conditions, air bubbles, which are blown through a pulp, attach selectively to the valuable particles (e.g., various sulfides) and float to a froth which is skimmed off and collected as concentrate. This flotation (⟶ Flotation) process is carried out in cells, columns, and air-sparged hydrocyclones. As

sufficient concentration cannot be achieved in one unit alone, they are arranged in banks which are interconnected so as to produce maximum recovery.

Magnetic and Electrostatic Sorting (⟶ ; ⟶). These techniques (wet or dry) utilize the magnetic (e.g., with magnetite), electrical conductive, and induced electrostatic properties of various minerals and materials to separate the valuable mineral or material from the surrounding gangue. This occurs mostly in rotating drumlike units arranged into suitable circuits. Electroosmosis, on the other hand, produces a separation between two electrodes.

X-Ray Sorting (⟶). When certain materials (e.g., diamonds) are irradiated by X-rays they become luminous and, hence, can be detected electronically and sorted from the gangue material.

Solid – Liquid Separation. The recovery of solids from liquid media, either to clarify solutions for hydrometallurgical treatment or to dewater pulps for pyrometallurgical operations, can be performed in drum, leaf, and sand filters (⟶ Filtration), thickeners, as well as decanting and centrifuging processes.

Gas Cleaning. Gas cyclones, bag filters, and electrostatic precipitators (⟶ Dust Separation) are used to clean gases or to recover valuable minerals from flue gases from pyrometallurgical operations, before they are vented to the atmosphere.

3.3. Agglomeration (⟶ Size Enlargement)

If the particle's size is too small for use in subsequent metallurgical unit operations, it is agglomerated into larger, more suitable lumps of appropriate size and strength. The unit operations used to achieve this objective are briquetting, pelletizing, sintering, and nodularizing.

Briquetting. Ore fines are mixed with a suitable binder and mechanically pressed into a suitable shape at room or higher temperature. The briquettes may subsequently be hardened in a kiln.

Pelletizing. A suitable binder and water are added to the ore fines, which are fed into a inclined rotating drum or disk. These green pellets may subsequently be fired in a furnace to increase their strength.

Sintering. Coal dust (5 – 6 %), ore fines, and water are mixed and fed onto the grate of a sinterstrand. The carbon in the sinter bed is ignited, and air sucked or blown through the bed produces an ignition front which facilitates drying, calcination, volatilization of the compounds in the bed, and fusion of the materials in the bed, imparting strength to the sinter. If sulfides are roasted and sintered, no carbon need be added.

Nodularizing. The same feed materials used for sintering are fed to an inclined rotating drum at an elevated temperature to produce nodules.

[Top of Page]

4. Pyrometallurgy [18]

Pyrometallurgical processes are used for the treatment of concentrates and ores to effect the following changes:

1. Conversion of certain compounds in ores and concentrates into other compounds
2. Separation of components and enrichment of valuable metals in certain phases
3. Reduction and refining of metals

All of these processes are characterized by high temperatures (200 – 3000 °C), large production rates (up to 10 000 t/d), and fast reaction rates.

Pyrometallurgy is discussed here under feed preparation and metal reduction. Refining is treated in Chapter Metal Refining, because it also includes hydrometallurgical processes. Each of these topics is discussed with reference to appropriate examples. The interrelation of these steps is depicted in Figure 3. An enrichment step is sometimes necessary before reduction can take place. Figure 3 shows that slag and flue dust are often recycled to recover their valuable metal content. The aforementioned steps, as they are applied in various pyrometallurgical operations in practice, are summarized in Tables 3 and 5).

Figure 3. Scheme for pyrometallurgical metal production

4.1. Feed Preparation

Ores and concentrates often do not have the optimum composition and physical state that is required for direct metal production. Thus, a certain amount of feed preparation is necessary. This includes drying (water removal), calcining (removal of hydroxide and/or carbonate), roasting (removal of sulfur as SO_2), and sintering to agglomerate fines to lumpy material. These processes concentrate the valuable compound only marginally, which makes separation of gangue and worthless

components from the metals worthwhile before reduction. This *enrichment* is done in several processes:

1. **Matte smelting** for copper or nickel enrichment in a sulfide phase (⟶ Copper – Pyrometallurgical Principles, ⟶ Nickel)
2. **Waelz process** for lead – zinc volatilization from different low-grade feeds into a high-grade Waelz oxide (⟶ Lead – Products of the Lead Blast Furnace)
3. **Slag reduction** of copper – nickel slags for final metal recovery
4. **Slag fuming** for lead – zinc – tin volatilization from slags into a fuming oxide (⟶ Lead – Products of the Lead Blast Furnace)

4.2. Reduction

Reduction of metal compounds takes place with oxides, chlorides, and sulfides. Reducing agents for oxides include coke for iron and lead oxide, hydrogen for tungsten trioxide, silicon for magnesium oxide, reactive metals such as sodium for $TiCl_4$ (Kroll process; ⟶), and sulfidic sulfur and oxygen (via intermediate formation of SO_2) for sulfides (copper converting, ⟶ Copper – Discontinuous Matte Conversion).

In these pyrometallurgical operations energy is necessary for heating and phase separation, and in the production of metal, energy is also required for the reduction steps. In many cases, the energy is available as chemical energy and the process may need no additional energy from external sources, as can be seen from Table 3.

Table 3. Process steps for pyrometallurgical operations

Reaction	Reactor	Metals	Energy source
Feed preparation			
Drying	rotary kiln	different	hydrocarbons
Calcining	fluidized bed, rotary kiln	Al	hydrocarbons
Roasting of sulfides	fluidized bed	Zn	autogenous with air
	multiple hearth	Mo	
Sinter roasting of sulfides	DL-sintering machine	Pb, PbZn	autogenous with air
Sintering of oxides	DL-sintering machine	Fe	coke
Enrichment			
Matte smelting	flash smelter	Cu, Ni	autogenous with air
Slag reduction	electric furnace	Cu, Pb	electric and coke
Slag fuming	fuming furnace	Pb, Zn	coal
Waelz process	rotary kiln	Pb, Zn	coal
Metal production			
Reduction with carbon	shaft furnace	Fe, Pb, PbZn	coke
Metallothermic reduction			
Oxides	various reactors	V, Mg, Cr	Al, FeSi
Chlorides	retort furnace	Ti, Zr	Na, Mg
Reduction with hydrogen	retort furnace	Mo, W	H_2– heating
Electrochemical reduction	electrolytic cells	Al, Mg	electrical
Conversion of sulfides	converters	Cu, Ni, Pb	autogenous
	flash smelter	Pb, Cu	autogenous

[Top of Page]

5. Hydrometallurgy [19-22]

Most hydrometallurgical operations commence with leaching during which the valuable exposed or liberated minerals go into solution. This initial step is then followed by various processes that purify the leach solution and finally precipitate the valuable metal(s) as compounds or elements in a series of controlled steps. These metallurgical processes are discussed under the headings leaching, solid – liquid separation, purification and precipitation, and metal production. The interrelation of each of these aspects is depicted in Figure 4.

Figure 4. Scheme for hydrometallurgical treatment

5.1. Leaching (⟶ Liquid–Solid Extraction)

During leaching, the valuable mineral and other associated minerals are dissolved by an appropriate reagent under certain conditions (e.g., pH). Usually Pourbaix diagrams (⟶ Liquid–Solid Extraction) can give an indication of which leaching conditions are appropriate. Typical leaching reagents and reactions are:

1. water for water-soluble compounds (copper sulfate);
2. sulfuric, hydrochloric, and nitric acids or sodium hydroxide for metal oxides;
3. complexing agents e.g., cyanide (gold, silver) or ammonia (copper – nickel minerals);
4. reduction of a mineral by a suitable gas or oxidation, for example, manganese dioxide by sulfur dioxide, and
5. acid – base reactions, e.g., recovery of a tungsten complex from tungstates at high pH.

Bacterial leaching techniques involving microorganisms (e.g., *Thiobacillus ferrooxidans*) have been used to increase the leaching rates of various sulfides.

The physical method used to facilitate the leaching depends on the ore size, leaching rate, ore composition, and subsequent isolation and precipitation techniques.

Heap and Percolation Leaching. For particles in the size range of 6 – 200 mm, heap and percolation leaching techniques may be used. The leaching rates and recoveries, however, are not very high for these processes.

Agitation Leaching. Agitation leaching is more efficient than the two aforementioned techniques and is most widely used. In agitation leaching, the fine particles of a pulp – leaching reagent mixture are suspended in stirred tank reactors using either mechanical agitation (impellers, paddles, or turbines) or compressed air in Pachuca tanks. This process can be performed batchwise or continuously in a train of reactors.

Pressure Leaching. When the aforementioned techniques do not produce sufficient leaching rates, pressure leaching can be performed at elevated temperature [e.g., the Bayer process in which bauxite is leached (⟶ Aluminum Oxide – History and Procedure)].

In Situ Leaching. In situ leaching is performed at the ore body in the mine; the ore is flushed with an appropriate leaching reagent and the leach solution is collected for subsequent hydrometallurgical treatment.

Solid – Liquid Separation. After leaching and precipitation, various leach residues, gangue materials, or valuable compounds must be separated from the liquid phase. Various solid – liquid separation techniques are mentioned in Chapter Material Concentration .

5.2. Purification and Enrichment

During leaching a number of elements, in addition to the main element, go into solution which could affect the downstream processes or the final product quality. A variety of hydrometallurgical purification and enrichment techniques exist which could be used to produce suitable leach liquors, e.g., precipitation (crystallization), ion exchange (including carbon-inpulp/leach), solvent extraction, reverse osmosis, and ultrafiltration. Once the raw leach solutions have been purified and the appropriate metallic ions isolated or concentrated, they can be recovered by the methods discussed in Section Metal Recovery.

Purification.
Crystallization (⟶ Crystallization and Precipitation). Depending on the concentration of gangue ions in solution, appropriate selection of temperature and pressure can render the solution saturated; hence crystallization of these ions can occur, and they can be separated from the valuable leach liquor by solid – liquid separation techniques.

pH and Potential Control. By controlling the oxygen partial pressure, the potential, and the pH of a solution, specific ions may be selectively precipitated as sulfates, sulfides, or hydroxides, or partially reduced into more suitable ionic species. These precipitates are separated from the liquor by solid – liquid separation techniques.

Enrichment.
Ion Exchange. Various ion-exchange resins and fibers have been developed onto which cationic and anionic groups are loosely bonded; these can be replaced by appropriate metal ions, when the latter pass over these resins and fibers. These extracted metal ions can subsequently be reclaimed by stripping the resin or fibers with a suitable solvent. An example is the recovery of uranium from leach liquors. Activated carbon has a similar function and can be used to adsorb various metal ions and complexes from solution in continuous or batch stirred tank reactors. The carbon-in-pulp/leach process is applied, e.g., in the gold industry (⟶ Gold, Gold Alloys, and Gold Compounds – Recovery of Gold with Carbon).

Solvent Extraction (⟶ Liquid–Liquid Extraction). Some organic solvents that are immiscible with water can selectively extract certain metal ions and complexes from aqueous solutions. Examples of these extractants are

1. solvating extractants, which render certain metal ions neutral and hence soluble in organic solvents by solvation;
2. cation-exchange extractants (⟶ Liquid–Liquid Extraction – Introduction), i.e., organic acids in which hydrogen ions can be replaced by metal ions (⟶ Liquid–Liquid Extraction – Phosphoric, Sulfonic, and Carboxylic Acids.);
3. anion-exchange extractants (⟶ Liquid–Liquid Extraction – Introduction), in which metals present as complex metal anionic salts in solution are exchanged for chloride anions present as organic salts in the organic solvent (e.g., amines ⟶ Liquid–Liquid Extraction – Amine and Phosphine Salts.); and
4. chelating extractants (⟶ Liquid–Liquid Extraction – Introduction, ⟶ Liquid–Liquid Extraction), in which the organic compound forms an organometallic complex with the metal ion.

The valuable metal ions are subsequently recovered by various stripping techniques from the organic phase and the extractant is regenerated.

Reverse Osmosis (⟶ Membranes and Membrane Separation Processes – Principle of Reverse Osmosis). When a pressure in excess of the osmotic pressure is applied to a concentrated leach solution, water passes from the concentrated to the dilute solution (water), which is separated from the concentrated one by a semipermeable membrane. This leaves the metallic ions in a more concentrated form and suitable for subsequent precipitation.

Ultrafiltration (⟶ Membranes and Membrane Separation Processes – Principle of Ultrafiltration). Ultrafiltration involves selective sieving of molecules (M_r > 500) through the pores of a membrane, external pressure being the driving force.

5.3. Metal Recovery

A metal may be recovered from the leach solutions either as a compound or as an element. These aspects are discussed under precipitation and reduction, respectively.

Precipitation.
Crystallization and pH Control. The same discussion of enrichment and purification is true here also, but with reference to the valuable metal ion to be recovered. Examples are the production of aluminum hydroxide from bauxite ores via the Bayer process or the precipitation of ammonium paratungstate as discrete crystals under favorable conditions of temperature, pH (rate of addition of base), and agitation.

Reduction. Precipitation of the valuable metal in metallic form may be achieved by various methods, all of them involving an oxidation – reduction reaction.

Cementation. Cementation involves the oxidation of a less noble metal (more anodic) by a more noble metal (more cathodic) ion in solution, e.g., precipitation of copper ions in solution by iron or zinc which go into solution and zinc cementation in the older gold-processing technology or in zinc solution purification.

Gaseous Reduction. By bubbling appropriate gases (e.g., hydrogen) through solutions containing metal ions (e.g., reduction of nickel from ammine solutions), selective reduction can be achieved if the pH, the hydrogen partial pressure, and the activity of the metal ion are controlled.

Other gases that are used are hydrogen sulfide, sulfur dioxide, and carbon monoxide, e.g., the Mantos Blancos process utilizes sulfur dioxide to produce copper(I) chloride from atacamite leach solutions (⟶ Copper – QS Process).

Electrolysis. Metals can be recovered from their aqueous solutions by electrolysis. This involves deposition of the required metal on a suitable cathode constructed either from the metal being recovered or from a suitable alloy which provides a high hydrogen overpotential. The anode is usually chosen so that it does not dissolve during electrolysis. However, during electrolytic refining, anodes are made of the same metal that is being recovered; copper and zinc electrolysis are typical examples. Other applications of electrolysis are discussed in Chapters Electrometallurgy and Metal Refining.

[Top of Page]

6. Electrometallurgy [23, 24]

Electrometallurgy includes all processes that employ electrical energy for metallurgical purposes; hence, it is employed in both pyro- and hydrometallurgy. The two principal applications are electrochemical metal production and refining, and heating.

In this chapter only the electrolysis of fused salts is discussed (for aqueous electrolysis, see Chap. Hydrometallurgy).

6.1. Electrochemical Metal Production

Electrochemical reduction is used for metals with very low reduction potential, so low that they cannot be recovered from aqueous solutions. Hence, these metals are recovered via the electrolysis of fused salts; examples are aluminum, magnesium, titanium, and alkali metals. All these processes require pure salts as feed material (e.g., Al_2O_3, $MgCl_2$, $TiCl_4$, NaCl, and KCl), to avoid co-reduction of impurities. This type of operation is conducted at 600 – 950 °C, the heat originating mainly from the ohmic resistance of the melt. The electrolytes are fluorides and chlorides.

Electrochemical reduction produces metals of very high purity, but at a very high energy consumption and a low production rate, if compared to pyrometallurgical methods.

6.2. Electric Furnace Operation

Electric furnaces (⟶) are used in the pyrometallurgical process industry during metal production (see Table 4). Further applications are in the fields of metal and alloy melting (see Table 5).

Table 4. Metallurgical application of electric furnaces

Smelting	Metals
Smelting of ores	FeNi
Smelting of concentrates	CuNi
Reduction of ferroalloys	W, Mo, V, Cr, Si, Mn
Production of special materials	P, graphite, SiC, CaC_2, Ca_2Si

Table 5. Electric furnaces for metal melting

Metal melting operation	Open furnace	Vacuum furnace
Arc	steel	steel, Ti, superalloys
Plasma	steel	Ti
Induction	steel, Cu, Al, Ni, Zn	steel, Ni, superalloys
Resistance (electro slag refining)	steel	
Electron beam		steel, Nb, Ta, Ti, V, Zr, Hf, superalloys

The advantages of the application of electrical furnaces can be summarized as follows:

1. Very high temperatures can be reached.
2. Energy density is high.
3. High product purity and production rate can be achieved.
4. Metals of uniform composition can be produced.
5. Any desired atmosphere may be applied.
6. Waste gas volume is small; hence, environmental control is easier.

[Top of Page]

7. Metal Refining

Every metal produced by either pyro- or hydrometallurgical methods contains various amounts of impurities. Depending on the application of the metal, the impurity content must be lowered to levels determined by product specifications set by the user. These impurities may be divided into two groups i.e., those elements that are economically recoverable and secondly, those that have little economic value. Refining can be achieved by following a pyrometallurgical or a hydrometallurgical route. This, however, depends on the product specification or the economic value of the byproducts. A general refining scheme cannot be presented (Fig. 5 gives a simplification), but common refining methods are listed in Table 6.

Table 6. Common refining methods and examples

Pyrometallurgical	Hydrometallurgical
Physical methods	
Liquation (Pb, Zn)	Crystallization (Al, W)
Zone melting (Si, Ge)	
Distillation (Zn)	
Degassing (steel, Al)	
Vacuum melting (steel, Co – Ni alloys, Nb, Ta, V, Ti, Zr, Hf)	
Filtration (Al)	
Chemical methods	

Oxidation (steel, Cu, Pb)	Electrolytic refining (Cu, Pb, Au, Ni, Ag)
Chlorination (Al)	Precipitation (jarosite, Cu_2Cl_2)
Sulfurization (Pb)	Cementation (Cu, Co, Cd by Zn)
Formation of intermetallic compounds (Pb, Sn)	Solvent extraction (Cu, Zn, Co, Zr – Hf)
Deoxidation (steel, Cu)	
Electro slag refining (steel)	Ion exchange (U)

Figure 5. Scheme for metal refining

Some of the more common metals are refined *after* reduction (e.g., Cu, Ag, Au, Pb, Sn, Zn, and Fe), others must be purified *before* reduction (refractory metals, platinum group metals, rare earths, CoNi, Al, Zn) because their properties are similar to other metals associated with them (see Fig. 5).

Pyrometallurgical refining is generally fast, but not very selective, whereas hydrometallurgical refining has high selectivity, but usually lower production rates. Each of these routes is discussed separately and illustrated by appropriate examples.

7.1. Pyrometallurgical Methods

Pyrometallurgical methods may be subdivided into two paths: i.e., physical and chemical methods.

Physical Methods.
Liquation. Liquation is a rough separation process, mostly for nonferrous systems, where large concentration differences exist either between immiscible liquids or between solid and liquid phases, which are in equilibrium with one another. It is carried out by slow cooling of the liquid metal mixture in hearth furnaces or steel kettles. An example is copper liquation from liquid lead, which may be explained in terms of the low melting point eutectic mixture which exists in the copper – lead system at 99.94 wt % liquid lead: if the mixture is slowly cooled down to about 350 °C, most of the copper separates out on the surface of the lead and can thus be recovered (⟶ Lead – Pyrometallurgical Refining).

Zone Melting. Metals of very high purity are produced from solid metals by this method. A small molten zone is moved along a bar or rod of the feed metal. The ensuing concentration difference between the liquid and solid phases produces enrichment of the impurities in the moving liquid zone.

Distillation. Due to the difference in the vapor pressure of various components within a metal mixture, one or more of the more volatile components evaporates preferentially from the metal melt. The distillation and the bottom (distillation residue) products are recovered. The rate of distillation can be increased by the application of vacuum techniques. Liquid mixtures of metals with small differences in vapor pressures are separated by rectification.

Degassing. Product specifications require low levels of dissolved gasses in the final metal product, especially hydrogen, nitrogen, and oxygen, which must be removed. Carrier gas degassing and vacuum degassing are well-established techniques.

Vacuum Melting. Extremely low levels of impurities may be produced in metals and alloys if they are melted under vacuum. This achieves degassing and volatilization at the same time.

Filtration. Metal melts can be filtered to remove floating solid particles, which occur as oxides, carbides, and nitrides.

Chemical Methods. Compounds formed from dissolved impurities in the melt by chemical reactions can be separated from the melt by physical methods. This is the most widely used technique for metal purification. The compounds which are formed may be either in the solid, liquid, or gaseous state.

Oxidation, Chlorination, and Sulfurization. Under oxidizing (sulfurizing or chlorinating) conditions, the impurities in the melt may be removed as oxides (sulfides, chlorides), because their affinity for these substances is higher than that of the base metal. The oxidation product is usually dissolved by a slag or salt melt, which can easily be removed from the metal bath. Oxygen is fed to the melt as pure gas, as air, or in the form of an oxidizing agent; chlorine as gas or salt, and sulfur in its elemental solid state.

Deoxidation. Dissolved oxygen may be removed from melts by the addition of deoxidizing agents such as carbon, hydrogen,

or reactive metals and by formation of the corresponding oxides (e.g., CO, CO_2, H_2O, and Al_2O_3).

Formation of Intermetallic Compounds. Removal of an impurity from a liquid metal can be effected by precipitation of intermetallic compounds. This is performed by dissolving sufficient amounts of particular metals, which subsequently form such compounds with the impurities. After dissolution, agitation, and cooling, a crust of intermetallic phases is formed on the bath.

Electro Slag Refining. In this method a crude metal is refined by a molten slag that is heated electrically by resistance. The crude metal is usually a suspended electrode, the lower part being submerged in the molten slag bath. The molten metal forms droplets that fall through the molten slag, hence they are refined before collecting at the bottom of a water-cooled mold, from which the solid metal is recovered.

7.2. Hydrometallurgical Methods

Most of these methods are described in Chapter Hydrometallurgy , hence only electrolytic refining is discussed here.

Electrolytic refining is a common method for refining crude metals. The crude metal and impurities with a more negative potential (anode) are dissolved electrochemically and transferred to the cathode. Only the principal metal is deposited as a metal on the cathode. Metals with a more positive potential than the principal metal are not dissolved at all.

[Top of Page]

8. Metal Recycling

For economical and ecological reasons, recycling of various scrap materials (see Chap. Raw Materials and Products) is a very important aspect of extractive metallurgy. A general overview of various recycling routes is given in Figure 6.

Figure 6. Scheme for metal recycling

[Top of Page]

9. Fabrication Technology [25-29]

Designing materials with the required characteristics for a particular application from the refined metals falls into the realm of physical metallurgy. These materials subsequently follow various fabrication steps during which they are transformed into usable finished products. Figure 7 gives a brief overview of fabrication methods and steps.

Figure 7. Brief overview of fabrication technology

For a description of the various methods and applications, see ⟶ Foundry Technology; ⟶ Metal-Matrix Composites; ⟶ Metals, Surface Treatment; ⟶ Powder Metallurgy and Sintered Materials; ⟶ Soldering and Brazing; ⟶ ; ⟶ Aluminum Alloys – Thermal and Mechanical Processes ⟶ Aluminum Alloys – Production Methods for Aluminum Alloys; ⟶ Fibers, 5. Synthetic Inorganic – Metal Fibers; ⟶ High-Temperature Materials – Metallic Materials.

1. Introduction

In aerospace, automotive, and general engineering, new developments require new materials with a low density and improved properties. Thin, stiff, high-strength fibers embedded in a plastic matrix can be used for such applications (→ Composite Materials). In an increasing number of applications, however, the inherent properties of the plastic matrix (temperature stability, resistance to the environment, brittleness, strength, and stiffness) are not sufficient. Composite materials with a metal matrix, especially those with a low density, are becoming more important due to their significantly improved properties.

Figure 1. Tensile strength of glass fibers as a function of their diameter [2], [3]

The theoretical strength of crystalline or metallic bodies for all imaginable loading situations would be fully adequate if it could be achieved in practice. It is approximately 10 % of the modulus of elasticity (i.e., 5 – 50 GPa) and can be calculated from the energy required for splitting two atomic planes in the crystal lattice [1]. The theoretical strength cannot be achieved in practice, however, because even compact bodies made from specially produced materials have defects. These defects may be dislocations which cause plastic deformation and thus lead to ductile fracture, or the formation of crack nuclei in nonductile material followed by premature brittle fracture.

In 1920 A. A. GRIFFITH [2] observed that glass fibers increased in strength with decreasing diameter (Fig. 1), and concluded that this offered a way of attaining the theoretical strength. He proposed the so-called " fiber paradox" which states that "material in fiber form is stronger than in compact form and strength increases with decreasing thickness". In a compact brittle ceramic material with a defect density ϱ_d, the average defect distance is given by:

$$l = \varrho_d^{-3}$$

i.e., if $\varrho_d = 1000\,\mathrm{cm}^{-3}$ then $l = 1$ mm (Fig. 2 A) [3]. In fibers of diameter d with the same defect density, the defect distance is given by:

$$l = 4/\left(\pi d^2 \varrho_d\right)$$

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a16_389

i.e., when $d = 10\,\mu m$ then $l = 12.7\,m$ (Fig. 2 B). Such fibers can attain strengths of up to 5 GPa. Use of fibers thus allows production of a high-strength material. The fibers are spatially arranged and embedded in a suitable matrix which fixes the fibers, protects them, and transmits forces to the fibers.

Figure 2. Distance between defects in bulk (A) and fibrous (B) ceramic materials [3]

More detailed discussions of the definition, the classification, the reinforcement mechanisms, and the resulting properties of fiber-reinforced composites as well as a detailed description of fiber reinforcement of plastics are given elsewhere (→ Composite Materials).

The present article concentrates on the reinforcement of metal matrices due to the increasing importance of these materials. More detailed information can be found in [4–6].

2. Components

Metal-Matrix Alloys. The properties of composite materials depend on the matrix properties especially when the fiber content is low or when reinforcement is achieved with short fibers or particles instead of continuous fibers: this is often the case for metallic composites. Table 1 contains important properties of the light metal alloys most commonly used in metal matrix composites [7], [8]; due to their low densities, high specific values for the properties of the composite are possible. Methods to increase the high-temperature strength of the nickel superalloy Nimonic 90 [9] by fiber reinforcement have been currently being investigated. Carbon steel and an epoxy resin are listed for purposes of comparison.

Continuous Inorganic Fibers. Due to the required high-temperature and chemical resistances of the fibers to the matrix alloy during production and also at the use temperatures, only ceramic fibers based on the thermodynamically stable oxides and carbides of light elements (high-silica, high-quartz, alumina, and silicon carbide fibers) can be considered. A summary of the composition and properties of the most important of these fibers is given elsewhere, → Composite Materials, Chap. 4.1.3., see also → Fibers, 5. Synthetic Inorganic, Chap. 3.4.1.

Short Fibers, Whiskers, and Particles. In addition to classical reinforcement with continuous fibers, reinforcement of metals with short fibers, whiskers, and ceramic particles is becoming more important. These composites can be further worked using techniques such as forging or extrusion. The short fibers can be cut from long fibers or produced by similar techniques to staple fibers. Aluminum hydroxide, for example, is spun in a sol – gel process to form bundles of short filaments. These gel-like filaments are dehydrated, dried, and calcined at high temperatures.

Whiskers are short, microscopically fine, single-crystal fibers produced by gas-phase reactions at high temperatures (→ Whiskers). As a result of their small diameter ($< 1\,\mu m$) and the fiber paradox (Chap. 1), they possess very high strength; Table 2 gives typical properties.

Fine ceramic particles (powder with a particle size $\leq 20\,\mu m$) are less expensive and are being introduced as a reinforcing material [10]. Their reinforcement effect is based on a different mechanism–fine grain hardening and strain hardening of the matrix (cf. Section 3.2).

3. Mechanics of Reinforcement

3.1. Continuous Fibers

The modulus of elasticity and the tensile strength of unidirectional, continuous fiber composites can be calculated, with a good approximation, using the linear "rule of mixtures" (→ Composite Materials, Chap. 3.2.). A linear relationship exists between the tensile strength

Table 1. Properties of commonly used matrix alloys and related materials

Material∗	Density (ϱ), g/cm^3	Modulus of elasticity (E), GPa	Tensile strength (R_m), MPa	Linear coefficient of thermal expansion (α), 10^{-6} K^{-1}	Reference

of the composite $\sigma*_c$ and the fiber volume fraction f:

$$\sigma_c^* = f\,\sigma_{F,\mathrm{eff}} + (1-f)\,\tilde{\sigma}_M \tag{1}$$

where $\sigma_{F,\mathrm{eff}}$ is the effective strength of the fibers and $\tilde{\sigma}_M$ is the matrix flow stress at fiber fracture (Fig. 3). However reinforcement above the matrix tensile strength $\sigma*_M$ only occurs when the critical fiber volume fraction (content) f'' is exceeded. For metal-matrix composites the effective fiber strength $\sigma_{F,\mathrm{eff}}$ is lower than the maximum fiber strength $\sigma*_F$ because of alignment problems of the fibers, orientation deviations, and insufficient bonding. The fiber efficiency factor η_F is defined by $\sigma_{F,\mathrm{eff}} = \eta_F \cdot \sigma*_F$ or after Equation (1) by

$$\eta_F = \frac{\sigma_{F,\mathrm{eff}}}{\sigma_F^*} = \frac{\sigma_c^* - (1-f)\,\tilde{\sigma}_M}{f\,\sigma_F^*} \tag{2}$$

When $\eta_F < 1$, the critical fiber volume fraction f'' must be increased to achieve the required strengthening (Fig. 3).

Figure 3. Composite strength $\sigma*_c$ as a function of fiber volume fraction f for continuous (l) and short discontinuous (s) fibers with different aspect ratios l/d (ROM rule of mixtures)
Symbols: $\sigma*_M$ = matrix strength; $\tilde{\sigma}_M$ = matrix flow stress; $\sigma*_F$ = maximum fiber strength; f'' = critical fiber volume fraction; η_F = fiber efficiency factor

3.2. Short Fibers and Whiskers

In short-fiber reinforcement the individual fibers do not carry the full tensile stress over their entire length. This is because this stress, which results from tensile and especially shear stresses in the fiber – matrix boundary surface, must be transmitted to the fibers. The stress from the fiber ends to the fiber centers can be described by the shear lag theory [1], [12]. A simplified representation can be seen for high boundary bonding strength and high tensile stresses when the matrix has exceeded its flow limit. The fiber ends transmit the tensile flow stress $\tilde{\sigma}_M$ and the fiber circumference the shear flow stress $\tilde{\tau}_M$ of the matrix (Fig. 4). Integration of this differential stress equivalency along the fiber

$$\frac{\pi}{4} d_F^2 \frac{d\sigma_F}{dx} dx = \pi d_F \tilde{\tau}_M dx \tag{3}$$

gives the average or the effective tensile strength of a fiber of length l (d_F is the fiber diameter, σ_F the tensile stress within the fiber, and x the length coordinate).

$$\text{For } l > l_c : \sigma_{F,eff} = \sigma_F^* \left(1 - \frac{l_c}{2l}\right) + \tilde{\sigma}_M \frac{l_c}{2l} \tag{4}$$

where l_c is the critical length and fracture is initiated by fiber breakage.

$$\text{For } l < l_c : \sigma_{F,eff} = \tau_M^* \left(\frac{l}{d_F} + 2\right) \tag{5}$$

where $\tau*_M$ is the shear strength of the matrix because fracture now occurs in the matrix.

Figure 4. Stresses and strains of short fibers in a ductile matrix
A) Displacement field and tensile flow stress $\tilde{\sigma}_M$ within the matrix; B) Shear flow stress $\tilde{\tau}_M$ of the matrix at the fiber interface; C) Tensile stress σ_F within the fiberSymbols: $\sigma*_F$ = tensile strength of fiber; $\tilde{\sigma}_M$ = tensile matrix flow stress at fiber fracture; x = coordinate of fiber length

The parameter l_c is the critical fiber length below which the tensile stress in the fibers can never reach the true fiber strength $\sigma*_F$

$$l_c = \frac{\left(\sigma_F^* - \tilde{\sigma}_M\right) d_F}{2\tilde{\tau}_M} \tag{6}$$

Using the Schmid's shear stress relationship, the shear flow stress can be related to the more easily measurable tensile flow stress of the matrix:

$$\tilde{\tau}_{\mathrm{M}} \approx 0.5\tilde{\sigma}_{\mathrm{M}} \quad \tau^*_{\mathrm{M}} \approx 0.5\sigma^*_{\mathrm{M}} \tag{7}$$

According to Equation (2) the effective fiber strength and thus the fiber efficiency η_{F} depend only upon the length to thickness ratio (l/d) of the fiber and the matrix flow stress $\tilde{\sigma}_{\mathrm{M}}$ – especially when $l < l_{\mathrm{c}}$. The composite strength $\sigma*_{\mathrm{c}}$ with short fibers is thus more dependent upon the matrix properties than with continuous fibers. The influence of fiber length is especially significant in the case of the critical fiber content f'' where $\sigma*_{\mathrm{c}} = \sigma*_{\mathrm{M}}$.

$$\text{For } l > l_{\mathrm{c}} \quad f'' = \frac{\sigma^*_{\mathrm{M}} - \tilde{\sigma}_{\mathrm{M}}}{\sigma^*_{\mathrm{F}}\left(1 - \frac{\sigma^*_{\mathrm{F}} d_{\mathrm{F}}}{2l\tilde{\sigma}_{\mathrm{M}}}\right) - \tilde{\sigma}_{\mathrm{M}}} \tag{8}$$

$$\text{and for } l < l_{\mathrm{c}} \quad f'' = \frac{\sigma^*_{\mathrm{M}} - \tilde{\sigma}_{\mathrm{M}}}{\left(\frac{l}{2d}\right) - 1} \tag{9}$$

This strong dependency of the critical (the minimum allowable) fiber content on fiber length is shown in Figure 5 for alumina (Saffil and FP) fibers in an aluminum alloy (6061) as matrix material.

Figure 5. Dependence of the critical fiber content on the length of short alumina fibers in aluminum alloy 6061 [13]

Figure 6. Axial strength of aluminum alloys reinforced with continuous silicon carbide fiber and whiskers at elevated temperature [31, a]
a) Al 6061 with 48 vol % SiC fibers aligned at 0 ° to the applied force; b) Al 6061 with 48 vol % SiC fibers arranged in four layers at 0 °/90 °/90 °/0 ° to the applied force; c) Al 6061-T6 with 16 vol % SiC whiskers; d) Al 6061-T6

3.3. Particles

In the case of particles (which can be regarded as very short fibers), fiber reinforcement does not occur even with a very high particle content. This is because the length of the particle is too short to transfer sufficient load by shear stresses from the matrix to the particle (cf. Eqs. 5 and 7). The observed high strength of such materials occurs because the particles increase the strength (i.e., flow stress) of the matrix. This increase in flow stress is due to several metallurgical mechanisms:

$$\Delta\tilde{\sigma}_{\mathrm{M}} = \Delta\tilde{\sigma}_{\mathrm{M}}(f) + \Delta\tilde{\sigma}_{\mathrm{M}}(V) + \Delta\tilde{\sigma}_{\mathrm{M}}(P) + \Delta\tilde{\sigma}_{\mathrm{M}}(HP) \tag{10}$$

where $\Delta\tilde{\sigma}_{\mathrm{M}}(f)$ is the increase of the flow stress that occurs because the total deformation of the material is restricted to the matrix volume share; $\Delta\tilde{\sigma}_{\mathrm{M}}(V)$ is the strengthening of the matrix caused by a reduction in the cooling stresses brought about by plastic deformation (these stresses are caused by the different thermal expansions that occur during production); $\Delta\tilde{\sigma}_{\mathrm{M}}(P)$ is the hardening of the matrix caused by particles hindering the movement of the dislocations (the Orowan mechanism) [14];

and finally $\Delta\tilde{\sigma}_{\mathrm{M}}(HP)$ is the hardening of the matrix where movement of dislocation groups is hindered by a fine grain-hardening effect (the Hall – Petsch effect) [14]. The last two of these four parameters are the most important. An increase in strength $\tilde{\sigma}_{\mathrm{M}}$ of only 0.5 MPa has been calculated for the Orowan mechanism in composites containing 16 vol % of short fibers with a diameter of 20 µm and a length of 100 µm. For very fine particles with a diameter of 0.1 µm, the corresponding increase is 70 MPa. This is due to the greater inhibition of the dislocation movement by finer dispersed particles with smaller interparticle distances. The Hall – Petsch effect increases the flow stress $\tilde{\sigma}_{\mathrm{M}}$ by 30 MPa both for the short fibers and the particles; this accounts for approximately half of the observed reinforcement.

Figure 7. Fatigue strength of continuous-fiber-reinforced aluminum alloy (a, b) compared to a nonreinforced high-strength aluminum alloy (c) [31, a]
a) Al 6061 matrix reinforced with 48 vol % 12-ply SiC fibers, room temperature, minimum to maximum stress ratio = 0.1, maximum tensile strength 1420 MPa; b) Al 6061 matrix reinforced with 48 vol % 12-ply SiC fibers, 100 °C, minimum to maximum stress ratio = 0.1, maximum tensile strength 1517 MPa; c) AlZnMgCu1.5F53 (7075T73), minimum to maximum stress ratio = 0

3.4. Mechanical Properties

One of the most important advantages of metal-matrix composites compared to polymer-matrix composites is their higher thermal stability. Whereas the latter undergo severe softening at 120 – 250 °C, especially in humid atmospheres, metal-matrix composites retain their mechanical strength up to ca. 400 °C (Fig. 6). This is particularly marked for materials reinforced with continuous fibers (curves a and b). The late softening is due to reduction of the shear strength of the matrix which gradually eliminates transfer of load from broken to intact fibers, and transfer back to the intact parts of the broken fibers. The effective number of load-carrying fibers therefore decreases with increasing temperature.

Although enhanced thermal stability is less pronounced in metal-matrix composites reinforced with whiskers (Fig. 6, curve c), distinct reinforcement occurs.

Resistance to mechanical fatigue is also drastically enhanced by reinforcement with continuous fibers (Fig. 7). Due to their high strength the fibers act as crack stoppers and dividers (by delaminating the interface) so that the crack energy is prevented from concentrating into one single sharp crack. This also applies to a lesser degree for metal-matrix composites reinforced with short fibers.

4. Interactions between the Metal Matrix and Reinforcing Material

4.1. Wetting and Chemical Reaction

Wetting. The effective strength of short fibers obeys Equations (4) and (5) only when the tensile (bonding) strength and shear strength of the fiber – matrix boundary are higher than the flow stress of the matrix. If this is not the case, then these lower strengths must be taken into account and lead to significantly lower effective fiber strength and thus lower composite strength (Eq. 1). The necessary high bonding strength depends upon a low boundary surface energy, i.e., the fibers or particles must be wetted by the liquid matrix alloy. Wettability is measured by the sessile drop technique in which a droplet of alloy smelt is placed on a plate of the fiber material in a high vacuum and the resulting contact angle θ of the droplet is measured [15]. The angle θ decreases with increasing wettability and approaches 0° for complete wettability. The wettability increases with increasing temperature and θ decreases [16]. For example, aluminum alloys at 900 – 950 °C exhibit a rapid decrease of θ,

i.e., wetting occurs. Wetting can be improved by using alloying additives to lower the surface tension of the alloy (e.g., bismuth, lead, and titanium in aluminum) [17].

Wetting is time dependent and follows an S-shaped time curve; a slow start is followed by a rapid rise and a slow approach to saturation for 100 % surface coverage [18].

Chemical Reaction. The bonding strength can generally be increased when the matrix reacts slightly with the reinforcing components to give strong chemical bonds. Thick brittle intermediate layers must not, however, be formed. Growth of these layers is diffusion controlled and thus exceptionally rapid in the critical starting phase. This can be controlled by adding the reacting alloying elements in small amounts. The bonding strength of alumina fibers in aluminum alloys, for example, can be significantly increased by adding small amounts of lithium or magnesium. During heat treatment, the additional element diffuses to the boundary surface and reacts partially with the fiber surface to form $MgO \cdot Al_2O_3$ (spinel) [3].

Chemical reaction between the fibers and a main alloying element can produce a brittle compound which damages the fiber; this is the case with boron and carbon fibers in aluminum alloys [19]. Damage can be controlled by coating the fiber surface to prevent diffusion. Coating can be performed by methods such as chemical or electrochemical deposition, sputtering, or chemical vapor deposition. During production of loading no significant fiber damage occurs [20]. In titanium alloys that are reinforced with silicon carbide fibers and used for high-temperature constructions, the silicon in the fibers reacts with the titanium to form brittle titanium silicide [21]. A thin diffusion-hindering layer (e.g., of titanium carbide or nitride) delays the reaction successfully and prevents damage during the high-temperature production phase. Auger electron spectroscopy has confirmed the presence of titanium, silicon, and nitrogen in the boundary surfaces.

4.2. Bonding and Composite Strength

In composite materials with continuous fibers in a ductile metal matrix, the bonding of the fibers (expressed by the tensile and shear strengths of the interface) has only a small influence on the strength of the composite under static load. This is because the fibers are much longer than the critical length necessary to ensure full force transmission (Eq. 6) even for low boundary surface shear strength. However the toughness of the composite (the resistance to crack advancement during static or dynamic loading) depends largely upon the boundary surface shear strength [22]. If a crack in the matrix is perpendicular to a fiber of high bonding strength ($\tau*_{\mathrm{M}} > \tilde{\tau}_{\mathrm{M}}$), the critical length l_{c} (Eq. 6) is smaller than the stress field of the crack tip, i.e., the fracture strength of the fiber is exceeded and the crack advances in a straight line through the fiber and the entire composite.

If the fiber has a low bonding strength, then l_{c} is larger than the stress field and the fiber does not break but delaminates. As in a brittle matrix material, the crack branches leaving the fiber intact to bridge and relieve cracks. Toughness is significantly increased. The static strength of the composite depends directly upon the shear strength at the boundary surface when the fiber strength or diameter varies widely [23]. The strength increases with $\tau*_{\mathrm{M}}$ and the more so the wider the variation of $\sigma*_{\mathrm{F}}$ or d_{F}. A further influence on the composite strength is the reaction layer at the interface which is formed during production or heat treatment. These irregular and thus notch-forming layers grow approximately following a $\sqrt{t}$ law. Above a certain thickness (i.e., reaction time), they can lower the composite strength, as shown in Figure 8 for titanium alloys with silicon carbide fibers [24]. This behavior can be quantitatively related to the increasing notch effect of the layer which leads to delamination of fibers with a low bonding strength and crack advancement in fibers with a high bonding strength [25].

In metal-matrix composites with short fibers or particles, a sufficiently high bonding strength is a basic requirement. This ensures that stresses are transmitted to the short fibers (Section 3.2) and that effective dislocation barriers are formed with particles (Section 3.3). Very high bonding strengths have been achieved in a tensile test on an AlMgSiCu alloy reinforced with silicon carbide particles [26]. The lower limit for the bonding strength at the beginning of delamination was 1690 MPa. This bonding strength re-

quires a boundary surface reaction with chemical bonding forces.

Figure 8. Fiber strength as a function of the annealing time (i.e., thickness of the reaction layer) for a titanium alloy matrix and fibers coated with boron (a) and boron – silicon carbide (b) [24]

Figure 9. Hot-pressed, six-layer composite (aluminum alloy reinforced with silicon carbide fibers, ×60) [3]
a) 100 µm SiC fibers with a tungsten core; b) Intermediate AlMn1 layers clad on both sides with AlSi12 brazing alloy; c) Surface layers of AlMn1 clad only on the inner side with AlSi12

4.3. Chemical Compatibility

During long-term high-temperature treatment either during production or in use, the boundary surface reactions may proceed so far as to damage or even destroy the components. In order to calculate the thermodynamic stability combinations of different components and alloys, the enthalpies of formation of the used and possibly formed compounds should be known. This is, however, only the case for ionic bonds; data are not available for the many intermetallic compounds with covalent and metallic bonds. Empirical rules must be used to estimate the resistance and the reactivity of major combinations of components or elements, for example, as given in Table 3. In many cases the stability of the system can be increased by using thin boundary surface layers of a thermochemically stable compound (e.g., by coating fibers with tantalum, titanium carbide, or silicon nitride). A further possibility is to use reactive elements in the matrix that reduce the diffusion of the basic system. This diffusion controls the time dependency of the compatibility relationships. Thus, thermochemically unstable systems can be used for composite materials as long as the reactions occur slowly enough. The composite will then be sufficiently resistant to reactions at the temperatures and times encountered during production and use.

5. Production

5.1. Sheets and Tapes

Highly loaded spatial structures such as tubes or supports can be made from thin strips or tapes reinforced with continuous fibers. The strips or tapes may be brazed or diffusion bonded in autoclaves. They are produced by *plasma spraying* an aluminum alloy onto a single fiber layer on a thin aluminum support foil [28]. Alternatively *hot pressing* or *hot rolling* of fiber gauze between plated aluminum sheet can be used [3]; multilayered composites in unidirectional or other orientations can be produced by this technique (Fig. 9). A low-melting (eutectic) aluminum – 12 % silicon brazing alloy (*mp* 573 °C) is plated onto the higher-melting matrix material (an aluminum alloy such as AlMn1, *mp* 630 °C) by hot and cold rolling. This allows subsequent oxide-free bonding of the fibers and welding of the matrix sheets. Below the melting point of the braze, the silicon in excess of the eutectic diffuses from the brazing alloy into the matrix and ensures that localized melting does not occur and that the composite is fully heat stable [29].

Table 3. Chemical compatibility of metal-matrix materials and fiber materials* [27]

Matrix (T_m, °C; ϱ, g/cm^3)	Fiber (T_M, °C; ϱ, g/cm^3)*						
	B (2050; 2.3)	C (3800; 1.7)	Mo (2610; 10.2)	W (3410; 19.3)	SiC (2500; 3.2)	Si_3N_4 (1900; 3.2)	Al_2O_3 (2030; 4.0)	ZrO_2 (2580; 5.4)
Mg (650; 1.7)							R>900 °C	R
Al (660; 2.7)	R>700 °C	R>500 °C			R>700 °C			R
Ti (1670; 4.5)	R>900 °C				NR<700 °C		R>1400 °C	R>1400 °C
Co (1500; 8.9)	R	R>1000 °C					R	
Ni (1450; 8.8)	R>600 °C	R>1000 °C	R	R<1100 °C	R>1100 °C	R>1100 °C	NR	NR<1800 °C
W (3410; 19.3)	R	R						NR
Nb (2420; 8.4)	R	R					NR<1800 °C	NR

* R = reaction; NR = no reaction; T_m = melting or decomposition temperature.

In another continuous hot rolling technique, a layer of fiber gauze is preheated to braze temperature (590 °C) between plated aluminum tapes under an inert gas prior to entry in the rolling gap [30]. The excellent orientation and bonding of the fibers means that the fiber-reinforced tapes have a very high strength and modulus of elasticity (Table 4, row 7). For a fiber content of 50 vol % the tensile strength R_m is ca. 1350 MPa and the modulus of elasticity $E > 200$ GPa, i.e., they exceed the values of steel. Even higher values can be otained by smelting and casting techniques (Section 5.2, Table 4). The transverse strengths, R_m (cr.d.), are naturally much lower than the values in the longitudinal fiber direction, R_m (l.d.), but still considerably higher than those of fiber-reinforced plastics (20 – 40 MPa, see → Composite Materials).

5.2. Cast Parts

Starting material for fiber-reinforced semifinished goods and fiber-reinforced engineering components can be produced by high-pressure smelt infiltration methods, e.g., squeeze casting [32] or pressure die casting with fiber preforms. Injection with aluminum can, for example, occur very rapidly in pressure die casting carried out under vacuum in a cold chamber machine (Fig. 10). Wetting problems do not occur and the boundary surface reaction necessary for good bonding can be achieved during subsequent heat treatment. The fiber preforms for this technique are cut from porous sintered plates of short fibers (e.g., of Al_2O_3 fibers) or are made from fiber

Table 4. Mechanical properties[a] of aluminum and magnesium alloys reinforced with continuous fibers [31]

Metal matrix[b]	Fiber	Fiber content, vol %	Production route	E, GPa	A, %	R_m(l.d.), MPa	R_m(cr.d.), MPa	T_{max}, °C	Reference

yarn or fabric that is bonded together with small additions of an inorganic binder and then sintered.

Fiber preforms (e.g., of FP fibers) for connecting rods are made from belts of continuous fibers for the shaft and the eyes, and short-fiber inserts for the stiffening of the shaft (Fig. 11 A) [3]. This and other techniques have been used to produce fiber-reinforced connecting rods from an ageable aluminum casting alloy AlSi10Mg (Fig. 11). Bonding of the fibers in the load-bearing section of the matrix is very good and they are evenly spaced, as has been confirmed by metallographic and microprobe investigations. Fiber reinforcement produces a significant increase in strength; the buckling strength for a connecting rod without reinforcement is 57 kN, reinforcing with 22 vol % alumina fibers raises the value to 149 kN [3]. The fatigue strength is, however, unsatisfactory probably due to poor fiber orientation. Weight saving as compared to steel is about 40 % and this factor also reduces vibration in the engine.

5.3. Semifinished Products

In the case of semifinished products which are to be subjected to hot deformation and are made from fiber-reinforced light metals (e.g., aluminum alloys), the starting material can be produced as described in Section 5.2 or by stirring or blowing the short fibers into the smelt [30]. Such material can be extruded to give simple shapes with a thin shell of fiber-free material. The fibers are orientated in the longitudinal direction so that virtually unidirectional reinforcement is achieved (Fig. 12) [30]. In conventional extrusion the fibers become fractured as a result of the high deformation forces. Fibers are thus shorter than the critical length (Eq. 6) and

full reinforcement is therefore impossible. This problem can only be solved using appropriate temperature control to extrude the alloy in a semiliquid state where the deformation forces are much lower [34]. Inspite of this handicap, the hot strength can be significantly improved. An aluminum – magnesium alloy with 16 vol % alumina has a strength of 120 MPa at 300 °C as compared to 60 MPa for a conventional piston alloy AlSi12CuMgNi [30].

Figure 11. Fiber preform of FP (alumina) fibers (A) for a diecast, fiber-reinforced aluminum motor connection rod (B) [3]

The relatively low reinforcement with short fibers can be explained with the rule of mixing (Eqs. 1, 4, and 5). If the effective short fiber strength is used for $\sigma*_{\mathrm{F}}$ in Figure 3, then according to Equation (5) the increase in strength with increasing fiber content is much less than for longer fibers with $l > l_{\mathrm{c}}$. A correspondingly higher critical fiber content is required to produce reinforcement.

Since the short fibers are heavily fractured in conventional extrusion and other hardening mechanisms become effective in the heterogeneous structure (cf. Section 3.3), many experiments have been undertaken to reinforce aluminum alloys with ceramic particles (e.g., silicon carbide and alumina) [35]. The particles are either injected into the smelt or mixed with the matrix powder and subsequently processed by powder metallurgy. With a particle content of 10 – 40 vol %, strengths are increased by up to 50 % and the modulus of elasticity by up to 100 %; wear resistance is also improved (Table 5).

Figure 12. Longitudinal section of hot extrusion rod composed of aluminum reinforced with short FP (alumina) fibers (×120) [30]

If the theoretical portion of the short fiber or particle reinforcement is subtracted from the composite strength, a higher strength than that of the pure matrix is often obtained [13]. This induced hardening of the matrix according to Equation (10) has been determined to be ca. 60 MPa for an aluminum – magnesium alloy reinforced with short fibers. For material reinforced with extremely fine particles or whiskers this additional hardening effect is much higher because the contributions $\Delta\tilde{\sigma}_{\mathrm{M}}$ (P) and $\Delta\tilde{\sigma}_{\mathrm{M}}$ (HP) in Equation (10) are the more significant the smaller the particles and the shorter the distances between them at constant volume fraction.

5.4. Hybrid Composites

In hybrid composites laminates of epoxy resins reinforced with a monolayer of unidirectional aramid fibers are sandwiched between thin, high-strength aluminum alloy tapes (ARALL, Fig. 13) [37]. The composite can consist of one or several aramid-fiber-reinforced plastic layers. The aramid fibers have a higher modulus of elasticity than aluminum, a much higher strength, and a small but significant fracture elongation. The fibers do not greatly improve the strength,

Table 5. Mechanical properties[a] of aluminum – magnesium alloys[b] reinforced with particles [36]

Matrix	Particles	Particle content, vol %	Production route[c]	E, GPa	A, %	R_m(l.d.), MPa	R_m(cr.d.), MPa	K_{IC}, N/mm$^{1.5}$	α, 10^{-6} K^{-1}
AlCuMg (2024)		0	IM and extruded	72	13	490		780	24
AlCuMg (2024)	SiC	10	IM and extruded	83	2.5	490		560	16

[a] E = modulus of eleasticity; A = plastic strain at fracture; R_m(l.d.) = tensile strength in longitudinal direction; R_m(cr.d.) = tensile strength in cross direction; K_{IC} = fracture toughness; α = coefficient of thermal expansion; Densities range from 2.7 to 3.3 g/cm^3 depending on type and amount of powder (cf. Table 2).

[b] Aluminum alloy designations are in accordance with the recommendations of the Aluminum Association, Washington, D.C.

[c] IM = ingot metallurgy; PM = powder metallurgy.

but dramatically increase fatigue strength parallel to the fiber direction. This is due to bridging and relieving of the crack tip by the undamaged fibers [38]. This mechanism works optimally when the fibers are not too firmly bonded in the plastic. The critical length of the fiber is larger than the size of the crack stress field. For biaxial loading the fiber layers can be crossplied.

Figure 13. Schematic structure of a 3/2 ARALL-2 laminate composed of three aluminum alloy layers (a), and two epoxy layers reinforced with aramid fibers (b) [38]

6. Working and Machining

Cast billets or sections of thick, extruded billets are die forgeable (Fig. 14). Fiber fracture is much lower than in small extruded cross-sections because the degree of deformation and the resulting stresses are much lower.

Figure 14. Forged compressor connecting rod made of aluminum alloy reinforced with short FP fibers [3]

Machining of metal-matrix composites (e.g., aluminum alloys reinforced with long and short alumina fibers) is possible with hard-metal cutting tools [39]. The life time of the tools can be raised by a factor of 100 when polycrystalline diamond is used as the cutting material. Surface roughness and dimensional stability are also improved due to the chip breaking effect of the fibers and the lack of pick-up on the cutting edge [39]. Other techniques such as grinding, turning, and milling with hard-metal tools produce similarly good results [3].

Table 6. Potential and realized technical applications of metal-matrix composites [11]

Application	Properties	Systems (reinforcement – metal matrix)	Production methods
Aerospace Structures			
Frames, stiffeners, antennas, fittings	high specific strength and stiffness, low coefficient of thermal expansion, high heat resistance	B – Al, SiC – Al, C – Al, C – Mg	melt infiltration (castings), hot pressing (tapes and sheets), diffusion and braze bonding (spatial structures)
Aircraft Structures			
Pylons, wing boxes, stiffeners, fan and compressor blades, transmission houses	high specific strength and stiffness, heat resistance, impact resistance	B – Al, SiC – Al, C – Al, SiC – Ti, Al_2O_3 – Al, Al_2O_3 – Mg	melt infiltration, hot pressing, diffusion and braze bonding
Turbine blades	high specific strength and stiffness, high heat and impact resistance	W – superalloy, directionally solidified eutectics, e.g., Ni_3Al – Ni_3Nb – Ni	melt infiltration, directional solidification of near net shape parts
Automotive Parts			
Frames, struts, connecting rods, pistons, piston pins, valve spring supports	high specific strength and stiffness, heat resistance, low coefficient of thermal expansion	SiC – Al, Al_2O_3 – Al, Al_2O_3 – Mg	melt infiltration, hot extrusion, forging
Battery plates	high stiffness	C – Pb, Al_2O_3 – Pb	melt infiltration
Electrical Equipment			
Motor brushes	high electrical conductivity, wear resistance	C – Cu	melt infiltration
Electrical contacts	high electrical conductivity, heat and corrosion resistance	C – Cu, Al_2O_3 – Al	melt infiltration, hot extrusion, forging
Technical Equipment			
Motorcycle and bicycle frames	high specific strength and stiffness, corrosion resistance	B – Al, SiC – Al, SiC – Mg	melt infiltration, hot pressing, braze bonding
Bearings	high specific strength and stiffness, wear resistance	C – Pb	melt infiltration, hot forming
Shuttles in textile machinery	high specific strength and stiffness, wear resistance	B – Al, SiC – Al, C – Al	melt infiltration, hot pressing, forging

7. Uses

Some uses of metal-matrix composites have already been mentioned in Chapter 5. Sheet and strip reinforced with continuous fibers have excellent properties and low densities (cf. Table 4). However, the production costs and fiber costs are presently so high that their use is limited to aerospace applications where the savings in weight and fuel consumption compensate the high production costs. An example here is the supporting structure of the U.S. Space Shuttle, made from aluminum tubes reinforced with silicon carbide fibers [40].

The aluminum sheets with a hybrid structure (ARALL) have lower production costs. They are being tested in aerospace applications; in cell constructions (e.g., in the lower side of an aircraft wing) where tensile loading is high [41]. Pressure die casting techniques using continuous and short fiber reinforcement of aluminum alloys are more economical methods of producing components. Various motor parts are presently being developed [3], [42] and some are already being produced and used (e.g., pistons, connecting rods, piston pins, and valve spring plates) [43]. Particle reinforcement of aluminum alloys is the cheapest method of production. Particle-reinforced components are being tested where high stiffness, hot strength, and especially good wear resistance are important (Table 6).

8. Occupational Health

During production and working with thin, inorganic (especially ceramic) fibers, fragments, and fine fibers, debris can escape into the atmosphere. As well as being a general inconvenience, this dust can be detrimental to health if inhaled. Investigations have shown that susceptibility to cancer depends upon the dimensions of the fibers. In cell culture tests very thin silicon carbide whiskers (diameter 0.1 – 1 μm) exhibit a similar toxicity as asbestos fibers (crocidolite) [44]. Tests using thicker alumina fibers (ca.

3 μm) show no significant shortening of cell life time. The same results also apply to equiaxial silicon carbide particles with similar thicknesses to the whiskers. They are only toxic when they have a large length to thickness ratio. The same protective measures must be used as for asbestos to prevent inhalation [45] (→ Asbestos, Chap. 9.

1. Introduction

This article describes methods for the treatment of metal surfaces. It is only recently that metal surfaces have attracted the attention of theoreticians and those concerned with practical applications. Metal surfaces are subject to both corrosion and mechanical wear. Bending causes the formation of surface cracks. Surface treatment of metals has an aesthetic value; decorative aspects play an important role.

Chapter 2 describes procedures for cleaning metal surfaces. Cleaning is increasingly important, not only as a finishing process for parts and components with decorative functions, but surface cleanliness is more and more accepted as a property to be maintained and controlled throughout the manufacturing line. At the same time European and national law tends to restrict the use of chemicals, including components of cleaning agents, not only with respect to nonaqueous solvents (volatile organic solvents, VOC), inflammable or explosive compounds, halogenated hydrocarbons, biocides as present in preservatives, etc., but also by making the process of registration and permitting of chemical compounds more difficult and expensive.

Efficient cleaning can determine the success of subsequent treatments (e.g., electroplating, thermochemical and plasma-assisted treatments). In many areas of manufacturing, like automotive, aircraft, and medical implants, cleanliness is an essential quality of both product and production line, because the technological properties of the final product depend on it. The most recent development is the definition of technical cleanliness and instructions for its measurement and evaluation [1].

Chapter 3 deals with phosphating which is finding increasing application. Chapter 4 is concerned with the case hardening of ferrous materials. The procedures described improve surface mechanical properties such as hardness and wear resistance, as well as flexural strength, fatigue strength, endurance limits, and corrosion resistance of the component. New developments in case hardening include increasing automatization and the use of laser, electron-beam, and plasma techniques.

Chapter 5 is concerned with spraying methods and spraying materials that are used to solve special problems, especially those caused by wear. Chapter 6 discusses the coloring of metals, which is used almost exclusively for decorative purposes.

Surface treatment of metals is a rapidly developing field and involves an ever-increasing variety of methods and processes, which include high-temperature processes like chemical vapor deposition (CVD, at ca. 1000 °C) and physical vapor deposition methods, mostly plasma-assisted, at lower temperatures (PVD, 400 – 500 °C). Developments in methodology and coating materials are also being made in PVD. Titanium nitride, titanium carbide, and titanium aluminum nitride are supplemented by other materials that are still being tested in the laboratory, for example, diamond-like carbon. CVD and PVD are no longer exclusively applied to metal-working tools, but also to structural components and medical implants. These techniques are described under → Thin Films. Ion implantation is used, among other applications, for producing thin, wear-resistant and/or corrosion-resistant layers.

Prevention of corrosion by surface treatment, including cladding and lining, is discussed in → Corrosion. The technique of electroplating is treated in → Electrochemical and Chemical Deposition. One application is the formation of corrosion-resistant barrier layers, but, depending on the properties of the coating, electroplated layers can also reduce abrasive wear, improve running properties, and have a decorative effect. Finally, the treatment of metal surfaces in its broadest sense includes application of paints and coatings (→ Paints and Coatings).

2. Cleaning

Surface cleaning is the removal of unwanted components, particles, and films. During manufacturing, workpieces and parts come into contact with a number of chemicals (lubricants, greases, anticorrosives, coolants, drawing or cutting oils, emulsions, etchants, deburring fluids, quenching agents, etc.). Machining is responsible for chips and cuttings; storage and transport lead to general soiling. Surface contaminants are less and less tolerated and must be removed. Although the binding forces between the substrate and an adhering particle or film are much lower than those present in a true chemical bond, en-

ergy input is needed to overcome the substrate – contaminant bond.

This energy input can be subdivided into three contributions: chemical, thermal, and mechanical energy. Thermal and mechanical energy are provided by the cleaning installation. The cleaning agent makes the chemical contribution. Conventional cleaning agents used in metal surface cleaning are aqueous or nonaqueous solvents.

Nonconventional cleaning processes apply carbon dioxide in the liquid (supercritical) or solid state with promising results. As the cleaning effect of the conventional agents is limited to loosely adhering contaminants and particles, a higher energy input is sometimes needed to remove reaction films and layers or even the first few nano- or micrometers of substrate. Then processes such as blasting, chemical or electrochemical etching/pickling, deburring, electrochemical machining (ECM), and plasma etching are applied.

Cleaning processes and agents, including aspects of environmental hazards and occupational health and safety, are in treated detail in databases, e.g., CLEANTOOL (http://www.cleantool.org), SAGE (http://clean.rti.org/), BAUTEILREINIGUNG (http://193.158.124.195/bauteile/portal/portal.-php), TURI (http://www.cleanersolutions.org/), SolventCentral (http://www.solventcentral.com/), and EPA Solvents Database http://solvdb.ncms.-org/).

2.1. Cleaning in Aqueous and Nonaqueous Solvents

2.1.1. Cleaning and Degreasing in Aqueous Media

As most soil and surface contaminants are insoluble in water, pure water is not an appropriate cleaning agent in metal surface cleaning. Additives can be distinguished by function and chemical composition. Classes of additives or components in aqueous cleaners are:

- *Builders*: inorganic salts of weak acids, which increase the pH of the solution responsible for removal of solid insoluble particles such as cuttings, chips, and dust.
- *Surfactants* or *detergents*, subdivided into anionic, nonionic, and cationic surfactants, are organic molecules containing both hydrophobic and hydrophilic groups that enable the formation of micelles in aqueous solution and the formation of films, either on the surface to be cleaned or at the oil/water interface of an insoluble oil droplet, thus modifying surface tension and facilitating the removal of oil film and the formation of an emulsion, owing to the stabilization of small oil droplets in the aqueous phase. Whereas cationic surfactants are generally not used in metal cleaning, anionic surfactants are represented by alkyl aryl sulfonates, and nonionic surfactants by polyaddition products of fatty alcohols and ethylene oxide (polyethoxylates or polyglycols), with tailored properties (e.g., critical micelle formation temperature, turbidity point, and antifoaming behavior) depending on polyethoxylate chain length [2].
- *Complexing agents* increase the solubility of metal cations and reduce the problem of precipitation of sparingly soluble metal compounds, including metal soaps and water hardness.
- *Anticorrosives* are salts of organic acids and amino compounds that protect both cleaning installation and the cleaned metal parts from corrosion.
- *Buffers* maintain constant pH even if there is an input of acids to the cleaning bath.
- *Preservatives*: the increasing biodegradability of cleaning agent components leads to problems with microbial fouling, especially when the temperature of the cleaning bath is reduced. The use of preservatives, however, is being increasingly restricted by European laws and regulations.

The preferred components in aqueous cleaners are multifunctional: phosphates, for example, are known for their excellent capability to stabilize a dispersion of solid particles, have pH buffer properties, and form complexes with metal cations; amines prevent corrosion and can act as preservatives; nonionic surfactants help to remove an oil film from the metal surface and protect the cleaned surface from corrosion. Builders and surfactants which exhibit a significant synergistic effect are preferred (Fig. 1) [2].

Figure 1. Synergistic action of builder (2 %) and surfactant (0.1 %) in degreasing [3]

Products normally contain mixtures of surfactants and builders, because no single representative can provide all of the desired properties in the complete formulation alone, i.e., foaming characteristics, emulsifying or de-emulsifying behavior, wetting properties, chemical stability, and cleaning action. Surfactants present in lubricant greases can pass into the cleaning bath, and this can have both beneficial and adverse consequences. Adverse effects include undesired foam formation in spraying operations or emulsification of the added lubricant. Beneficial effects include reduction of the treatment time or increased useful life of the bath. Surfactants must be biologically degradable in accordance with national regulations.

The so-called surfactant mechanism, with or without support of a builder, is based on the adsorption of surfactant and builder anions on the substrate, as well as on solid contaminants (builder anions) and hydrophobic films (surfactant molecules or anions). This leads to the modification of surface charge because of builder adsorption and to modification of surface energy or tension with respect to the oil film. Both effects weaken adhesive forces, so that the contaminants can be removed by mechanical energy, as in stirring, splashing, or ultrasound-assisted cleaning. Both builders and surfactants replace contaminants by adsorbed films of their own kind, by a mechanism significantly different from that of solvents. As all builders and many surfactants are nonvolatile and cannot evaporate (unlike solvents including water), they remain on the substrate surface after drying. The only method to avoid spots and films of cleaning agent residues is to rinse the parts diligently in deionized water (which may contain an anticorrosive).

Based on their behavior toward oils and lubricants, cleaners are classified as emulsifying or de-emulsifying, depending on whether a stable emulsion formed with the input oil or not. The de-emulsifying cleaners offer the opportunity to easily remove the input oil from the cleaning bath surface by simple phase separation.

Commercial products can be distinguished by their application pH as strongly alkaline (pH > 12), alkaline (9 < pH < 12), neutral (6 < pH < 9), or weakly acidic (pH < 6); see Table 1. From alkaline to neutral products, cleaning effectiveness decreases with decreasing pH, but neutral agents are increasingly popular owing to simpler storage and handling conditions with regard to environmental and health/safety regulations and less corrosion risk.

Table 1. Classification of aqueous cleaning agents for metals

Type of aqueous cleaning agent	Composition	Use
Strongly alkaline	alkali metal hydroxides, silicates, phosphates, complexing agents, surfactants	heavy-duty cleaning, removal of severe soiling, electrolytic degreasing, saponification of ester oils, particle removal
Alkaline	phosphates, borates, complexing agents, carbonates, surfactants	machined parts, removal of chips and cuttings, cutting oils and coolants/lubricants; precleaning
Neutral	surfactants, corrosion inhibitors, polyphosphates	removal of coolants/lubricants, anticorrosives etc., in rinsing baths for increased corrosion protection
Weakly acidic	acidic salts (hydrogenphosphates), surfactants	cleaning and phosphating (without coating)

Alkaline Cleaning Agents. Alkaline cleaning agents consist of a mixture of inorganic salts (called builders) and surfactants. The builders — alkali metal hydroxides, silicates, orthophosphates, condensed phosphates, borates, carbon-

ates — control the pH of the solution and intensify the action of the surfactants. They remove and help to disperse and emulsify contaminant particles, metal soaps, lubricants, oils, and greases.

What type of cleaning agent is selected depends on the substrate and on the type of surface contaminant. Alkali metal hydroxides and carbonates are used when fats and oils are to be saponified or if some form of chemical attack on the substrate (e.g., aluminum or zinc) is required. All electrolytic cleaners contain a high percentage of alkali to provide high electrolyte conductivity. Silicates have a high soil-removing capacity; they are suitable for removal of pigments and are preferred for difficult cleaning jobs. During cleaning, a thin layer of silicate is strongly adsorbed on steel, aluminum, and zinc; in the cases of aluminum and zinc this inhibits further attack by the alkaline solution [4]. Phosphates are typical multipurpose components; they have good soil-removing properties and reduce water hardness, aided by other complexing agents. Cleaning agents based on borates are used for aluminum and zinc-coated surfaces.

Neutral Cleaning Agents. Neutral cleaning agents usually do not contain inorganic components (builders). The formulations are based on a combination of surfactants (mainly nonionic), corrosion inhibitors for iron and steel based on fatty acids and amines, and inhibitors for nonferrous and light metals (triazide compounds). The pH of the aqueous solution is between 6 and 9.

Neutral cleaners have only mild cleaning properties and are not appropriate for heavy-duty cleaning, but have two advantages: 1) they are not prone to form low-volatility surface layers on the cleaned surfaces, and 2) they establish temporary corrosion protection if applied in the final bath of the cleaning installation, owing to a thin residual adsorbed film. Consequently, they can be used in simple single-chamber or single-step cleaning operations which do not provide a final rinsing stage; however, their cleaning effectiveness is limited.

Weakly Acidic (Passivating) Cleaning Agents. Acidic cleaning and passivating media are based on phosphoric acid or alkali metal hydrogenphosphates. Surfactants support the removal of soil, grease, oil, and metal fines, so that precleaning with a neutral or alkaline agent may not be necessary. The surfactants are nonionic and low-foaming, e.g., ethoxylated fatty alcohols. Liquid or powdered products are applied mainly by spraying, sometimes by dipping. In addition to grease removal, acidic alkali metal hydrogenphosphates create a bluish iridescent or gray iron phosphate layer (0.2–1.2 g/m^2) which adheres firmly to the conversion layer below. Because the coating thickness is of the same order of magnitude as the wavelength of visible light, very small variations give rise to color changes. The pH value of the cleaning solutions is between 3.5 and 5.5. They provide temporary corrosion protection as well as considerable adhesion, giving good bonding to organic coatings such as paints or resins. The final multilayer structure prevents corrosion and red rust. Weakly acidic cleaning media are used principally in the domestic sector, e.g., in the treatment of steel furniture, office furniture, and refrigerators.

2.1.2. Cleaning Agents Based on Organic Solvents

Industrial greases and lubricants used in metal machining are insoluble in water but readily soluble in organic solvents like hydrocarbons, halogenated hydrocarbons, alcohols, esters, and ketones, especially if the lubricants are based on mineral oils consisting of paraffinic, isoparaffinic, olefinic, or naphthenic hydrocarbons. Fatty ester based lubricants and emulsions have more limited solubility. Hence, organic solvents are used for surface cleaning and degreasing of metal parts. Most of the solvents are insoluble in water, but some systems are partly or completely miscible with water, for example, ester and alcohol derivatives.

One group of water-immiscible solvents are the halogenated hydrocarbons (HHCs), today comprising only chlorinated hydrocarbons. Chlorofluorohydrocarbons (CFCs), and especially 1,1,2-trichorotrifluoroethane (R113), are no longer used because of their ozone-depleting potential. Because of health and environmental risks, chlorinated hydrocarbons (CHCs) can only be applied in "zero-emission" plants [5]. To minimize the release of the volatile CHCs during transport, storage, and handling, special logistic concepts are available from suppliers. The advantage of CHCs is their flame resistance in

combination with excellent solubility for a broad variety of lubricants, oils, and greases, low boiling point, and low viscosity. Low surface tension enables them to penetrate narrow cleavages, capillaries, and bores. Low boiling points allow degreasing processes to be carried out in the vapor phase, and make the drying process simple.

Perchloroethylene and methylene chloride are nonflammable. The CHC most widely used in the past, because of its low price, trichloroethylene, must be replaced because of its carcinogenic potential [6]. Metal parts in a CHC-based degreasing installation should be dry, because CHCs tend to form hydrochloric acid in contact with water, oxygen, and light, which the causes corrosion of the cleaning plant and the cleaned metal parts. To prevent acid formation all CHCs contain stabilizers. As the stabilizer content decreases during operation, its concentration must be checked on a regular basis, so that stabilizer can be added if necessary.

Alternatively, hydrocarbon cleaners consisting of isoparaffins and naphthenes can be used. These solvents are inflammable and have flash points above 55 °C. Air and solvent vapor can form explosive mixtures, depending on composition. Their maximum working temperature is 15 °C below flash point [7]. However, even operating temperatures above the flash point are permitted if the danger of explosion is excluded owing to low-pressure or vacuum operation or the use of inert gases (e.g., during vapor degreasing). Drying installations are more complex, because of their low vapor pressures/high boiling temperatures (ca. 200 °C) and safety aspects. Although hydrocarbon cleaners have higher viscosities than CHCs, they have excellent degreasing characteristics, especially for mineral oil based contamination. Even insoluble contaminants such as chips and cuttings, pigments, metallic soaps, and inorganic solids (e.g., salt residues) can be removed from the surfaces if they are imbedded in soluble greases or lubricants. Hydrocarbon cleaners can be used as a dual-phase cleaner dispersed in water to increase the cleaning efficiency for hydrophilic contamination. After drying, the parts are temporarily protected from corrosion by a thin hydrophobic film on the surface.

Hydrocarbon cleaners are handled in closed installations. Solvent cleaners (provided they do not contain additives) have simple compositions compared to aqueous or surfactant cleaners. They contain no inorganic or organic salts and evaporate without residue at elevated temperatures.

2.1.3. Cleaning Process Technology

Cleaning efficiency is limited by process technology. Mechanical energy input plays an important role when parts with complex geometries (narrow clefts and bores) or bulky parts are treated. Mechanical energy input is realized by using ultrasound, spraying, or jet technologies. Especially when using aqueous cleaners, the appropriate cleaning agent must be selected with respect to foaming, ultrasonic stability, etc.

A multistep cleaning installation is illustrated in Figure 2. The cleaning of heavily contaminated parts requires a multistep cleaning installation with precleaning, cleaning, two or more rinsing baths, and a drying chamber. The precleaning stage removes heavy oil contamination and larger particles, so that the second cleaning bath is not overloaded with oils and lubricants. To save water, minimize waste, and ensure constant bath quality, all media within the cleaning installation should be treated and recycled. Efficiency is increased by managing all media throughputs in a cascade counterflow from lower to higher contamination, separately for the cleaning and the rinsing stages, so that contents of both contaminants and cleaning agents decrease from the initial to the final bath. Both cleaning baths should be treated by phase separation and micro- or ultrafiltration to separate insoluble and emulsified oils as well as particles in a bypass. Cleaning-agent concentration must be controlled in all baths. Diligent rinsing is crucial when aqueous, especially alkaline, cleaners are used, to remove nonvolatile cleaning-agent components which otherwise form milky-whitish layers or spots and can impede subsequent surface treatments [3].

Thus, at least one rinsing stage is necessary. Rinsing is performed with desalted or demineralized water. To prevent corrosion after drying, a corrosion inhibitor may be added to the second or the last rinsing bath. Attainable surface quality is limited by the composition (i.e., the degree of contamination) of the last rinsing bath.

Figure 2. Cleaning installation

Organic solvents, especially chlorinated hydrocarbons, are applied in closed or even zero-emission installations, where solvent emissions are minimized by low-temperature condensation (e.g., hydrocarbons), activated-carbon filtration, or gas-phase exchange (zero-emission plant) so that they obey European and national law.

Alternative processes under development are high-pressure processes using, e.g., supercritical carbon dioxide or hot air jets with or without water vapor, whose effectiveness will depend strongly on the type of soil or contamination to be removed.

2.2. Cleaning and Pickling with Salt Baths

Although aqueous media are increasingly preferred, even for difficult scale removal and surface conditioning, molten salt baths are still in use. The latter are mixtures of inorganic compounds used in their anhydrous fused state at elevated temperature (200 – 540 °C depending on composition and application). Their commercial applications can be divided into three main categories: heat-transfer media, active heat-treating baths for carburizing and/or nitriding, and chemically reactive melts. The last category is of interest in the molten salt bath cleaning of metals.

The main function of a metal-cleaning salt bath is to react with an undesirable impurity, coating, or oxide on the surface of a metal without adverse attack on the base metal. Examples of the wide variety of inorganic and organic surface impurities which may be effectively removed with molten salt baths include metal oxides formed during thermal treatment or forming operations, lubricants, plasma wear-resistant coatings such as tungsten carbide which must be removed from a component for rework or repair, organic deposits such as paints or polymers, or a ceramic residue from a casting operation.

2.2.1. Bath Composition and Properties

Molten salt baths are excellent reactive media for metal cleaning. High chemical activity, in combination with good solvency and fluidity, allow reaction with compounds that are resistant to conventional aqueous or organic solvents and chemical solutions, because of their elevated operating temperature and the absence of oxygen.

The composition of a bath is governed by many variables including melting temperature, application or end use, and long-term thermal

stability. Depending on its composition, a bath may be reducing, neutral, or oxidizing. Some proprietary neutral compositions may, however, be either reducing or oxidizing when activated with low-voltage, high-amperage direct current [8].

When operated in properly designed and engineered furnaces, most salt bath processes have very good longevity of operation and, unlike most aqueous systems, do not require complete dumping or recharge with continued use.

Most cleaning operations with molten salt generate byproducts with limited solubility in the host molten salt. Even at and beyond saturation, the molten salts continue to react with and to remove surface contaminants. The byproducts simply precipitate and can be conveniently and safely removed from the working bath via solids collection systems (Fig. 3) [9]. "Soluble" impurities do not usually reach a detrimental concentration; drag-out and make-up tend to prevent buildup.

Figure 3. Removal of reaction byproducts from a molten salt bath with a dedicated sludge zone

Fresh salt is added to the bath after solids removal to restore the bath to its original operating level and to maintain proper bath chemistry. Fresh salt additions may be added manually in the form of granular dry salts. For high-volume production applications (such as continuous strip annealling and pickle lines for stainless steel), regenerating salt may be automatically fed to the bath as a concentrated aqueous feed stream [10]. The chemistry of the bath usually does not require routine chemical analysis or adjustment to its composition; proper chemical balance and reactivity is maintained by removal of the byproducts from the bath and additions of fresh process chemicals to the bath.

2.2.2. Descaling of Metals

One of the largest applications for molten salt bath cleaning is the descaling of metals, e.g., stainless steels, nickel and cobalt-based superalloys, and titanium alloys.

Mineral Acid Pickling. Scale and oxide are removed from metals by pickling in mineral acid solutions. Commonly used mineral acids include sulfuric, nitric, hydrochloric, and hydrofluoric acids, used either alone or in combination. Sulfuric and hydrochloric acids are used for oxide removal from low-carbon steels, while nitric or combinations of nitric and hydrofluoric acids are used for oxide removal from higher-alloy materials such as stainless steels and superalloys.

As newly developed alloys are increasingly acid- and corrosion-resistant, their respective oxides and scales are increasingly acid-resistant as well. Much of the scale removal from these alloys by mineral acids is based on "undermining" of the oxide layer at the oxide – metal interface. By dissolving some of the base metal at the interface, the oxide layers are loosened and are either carried away by gases generated during pickling and/or by mechanical scrubbing or high-pressure water rinsing.

Although mineral acid pickling is satisfactory for low-carbon materials, it has numerous drawbacks when used on high-alloy materials. In most cases, the oxides formed on stainless steels and superalloys are much less reactive to mineral acids than the metal substrate. High acid concentrations and operating temperatures, in conjunction with long immersion times usually needed for complete scale removal, can lead to irregular roughening, pitting, and intergranular attack on the base metal. Economic and environmental concerns include long process times, short acid life, excessive metal loss, fuming, and waste-acid disposal costs and liabilities. Although mineral acid pickling is still an important and integral part of scale and oxide removal from these alloys, it is now often used together with molten-salt conditioning.

Molten-Salt Conditioning. Preliminary scale conditioning processes such as molten salt bath descaling allow subsequent mineral acid pickling operations to be carried out at substantially lower acid concentrations/temperatures and shorter immersion times while pro-

ducing superior results. For example, the acid pickling of austenitic stainless steels may require 15 % nitric and 5 % hydrofluoric acid at 60 °C, while after salt conditioning the same alloys can be cleaned with 10 % nitric and 0.5 % hydrofluoric acid at 45 °C and with a shorter immersion time. The loss of base metal is significantly reduced and the useful life of the pickling solution is extended.

Reducing salt baths based on sodium hydroxide and sodium hydride have also been used for descaling stainless steels. Sodium hydride was formed in a chemical generator by treating molten sodium metal with dissociated ammonia. The hydride was then added to molten sodium hydroxide to form the working bath. The hydride reduced the metal oxides to form metallic deposits on the metal surfaces.

Most descaling baths are of an oxidizing nature, comprising alkali metal hydroxides, alkali metal nitrates, oxidizing agents, and in some instances catalysts such as alkali metal chromates, vanadates, and manganates to provide a consistent, controlled reaction potential [11, 12].

Molten salts are very efficient for chemically modifying the tenacious oxide films formed on metals during thermal processing operations (e.g., forging, annealing, and stress relieving).

Components to be descaled are immersed into an oxidizing molten salt which operates in the temperature range 315 – 510 °C depending on application and composition. Reaction times are short, ranging from a few seconds to several minutes. A molten salt bath facility may be used either as a batch operation in which fixtures or baskets containing the workpiece are immersed sequentially into the molten salt, water rinses, acid brighteners, etc., or may be used for processing of metal strip as in a continuous annealing and pickling line.

Chemical Reactions. The scale-modification reaction is a two-stage reaction between the original metal oxide film and the molten salt. The metal oxide film is first oxidized from its initial low valence state to a high valence state by means of the oxidizing potential of the molten salt. The second stage involves reactions between the newly formed, high-valent metal oxides and other constituents of the bath to form both bath-soluble and bath-insoluble byproducts.

Low-valent chromium oxides, for example, are rapidly oxidized to chromium(VI) oxide, which in turn dissolves and reacts with the bath to form an alkali metal chromate:

$$CrO + O_2 \rightarrow CrO_3$$

$$2\,Cr_2O_3 + 3\,O_2 \rightarrow 4\,CrO_3$$

$$CrO_3 + 2\,NaOH \rightarrow Na_2CrO_4 + H_2O$$

Analogous reactions take place with many of the metals used in important alloy systems including stainless steels, nickel and cobalt-based superalloys, titanium, and tungsten.

Alkali metal chromates are soluble both in the molten salt bath and in water. On completion of the molten salt bath conditioning cycle, components are then "quenched" in water at ambient temperature. Quenching cools the metal to a safe operating temperature, assists in thermally "shocking" any heavy scale deposits off the metal surface, and dissolves the thin salt film and any water-soluble reaction products from the surface of the metal. Up to 80 % of the original oxide thickness is removed by salt bath conditioning.

After water quenching, a thin oxide film composed of bath-insoluble species is usually still present on the metal surface. Figure 4 shows an Auger surface scan of annealed 304 stainless steel before (A) and after (B) salt bath conditioning. The film remaining after conditioning is composed of iron oxide and minor alloy oxides. The oxides are in high valence states and readily dissolve in acid pickling compositions. Prior oxidation of the surface scale by salt bath conditioning allows subsequent pickling operations to be carried out with more dilute acids and at lower temperatures than are possible without salt bath conditioning. Pickling times with salt bath conditioning are also usually shorter.

Refractive Metals and Alloys. The alloying elements responsible for producing high-temperature oxidation resistance and chemical resistance (e.g., nickel and chromium) make descaling and pickling of high-temperature alloys difficult. These alloys are most beneficially treated in molten oxidizing salt baths. In nickel-based superalloys, thermal treatments such as hot working, heat treating, and welding promote the formation of acid-resistant nickel and chromium oxides. Elements such as yttrium which

Figure 4. Auger surface analysis of annealed, 304 stainless steel
A) As annealed, total dioxide thickness 650 nm; B) After salt conditioning, total oxide thickness 130 nm

lend cyclic thermal stability to protective oxide films for high-temperature oxidation resistance also complicate the metal cleaning task.

Titanium and Titanium Alloys. Descaling of titanium and its alloys is also aided by molten salt bath conditioning. Surface oxides which are formed during annealing, stress relieving, or hot forming operations are converted to the respective alkali metal compounds in a manner analogous to the oxidation of chromium oxide. Lubricant residues from forging or forming operations, such as vitreous coatings, graphite, boron nitride, and molybdenum disulfide, react with the oxidizing molten salt to form alkali metal silicates, carbonates, borates, and sulfates, respectively.

After water quenching and rinsing, residual surface contamination is removed from the titanium by acid pickling. The surface has a uniformly reactive surface after salt bath conditioning. This is especially important if the titanium is to be subjected to chemical milling either for α-case removal or for gage reduction. (A brittle α-phase surface layer may form on β-titanium alloys due to surface alloying with oxygen or other interstitial elements. Chemical milling selectively reduces the thickness of titanium components or removes the α-case with a mixture of 35 % nitric and 3 % hydrofluoric acid.) Acid pickling is usually accomplished by first pickling the salt-conditioned titanium in hot sulfuric acid to expose the base metal, and then in a mixture of nitric and hydrofluoric acid for chemical milling and brightening.

Carbon Steel. Molten salt bath treatment is of little benefit in descaling carbon steel and low-alloy steel. Although oxidizing molten salts react with iron oxides, the resulting high-valent iron(III) oxides have very low solubility in the bath. The oxide film developed on carbon steel does not dissolve in the bath, and the metal surface becomes passive to any further chemical reaction. The formation of a passive iron oxide film on low-carbon steels allows salt bath furnace equipment to be manufactured from this cheap and readily available material.

2.2.3. Casting Cleaning

Sand and ceramic materials are commonly used for pattern and shell making in the metal casting industries (→ Foundry Technology). Residual core sand and/or shell may be difficult to remove by mechanical methods such as shot blasting because of casting geometries, or by chemical methods because of poor reactivity in conventional aqueous chemical systems.

Molten salt baths react with many of the commonly used shell and core compositions, which generally contain a substantial proportion of silicon dioxide [13]. Suitable bath compositions must include alkali metal hydroxides and may

contain proprietary components that cause the bath to be more aggressive and to reject the silicates from solution more readily.

Silica reacts readily with molten alkali metal salts to form alkali metal silicates:

$$SiO_2 + 2\,OH^- \rightarrow SiO_3^{2-} + H_2O$$

Other common shell or core constituents are zirconium silicate and aluminum silicate, which are either unreactive or only react very slowly with the molten salt. They are stripped off as the silicon dioxide is dissolved by the bath and the shell integrity weakens. The ceramic composition must include some silicon dioxide if the molten salt bath cleaning process is to be effective within a reasonable amount of time and at a reasonable operating temperature.

Figure 5. Electrolytic cleaning of cast iron with molten salt — A) Original cast iron surface

The cleaning of iron castings is another example of the versatility of molten salt bath processing (Figs. 5, 6, 7, 8, 9). Oxidizing or reducing conditions can be created within a single neutral salt bath by applying direct current potentials. Apart from surface oxides, iron castings usually contain some "burned-in" core sand which may come free during use and cause failure in critical components (Fig. 4 A). In addition, free surface graphite on as-cast or as-machined surfaces makes bonding operations such as babbitting or brazing difficult. (Babbitting is the application of tin- or lead-based alloys to journal areas of a component to provide a low-friction bearing surface.) By cleaning the castings in an electrochemically activated molten salt bath, surface scale, residual sand, and exposed surface graphite can all be removed without any detrimental attack on the casting surface. No significant dimensional changes occur.

Figure 6. Electrolytic cleaning of cast iron with molten salt — B) After first reduction cycle

Figure 7. Electrolytic cleaning of cast iron with molten salt — C) After oxidation cycle

In the first step, the components to be treated are subjected to a cathodic potential at which oxides on the casting surface are electrochemically reduced, and any exposed sand particles are removed (Fig. 6 B). The polarity is then re-

versed to anodic, and a thin layer of iron oxide is formed on the metal surface, presumably accompanied by the oxidation of surface carbon to carbon dioxide (Fig. 7 C). A final reducing cycle yields an oxide-, sand-, and graphite-free surface (Fig. 8 D). When the cleaned casting is brazed or babbitted, a superior adhesive bond is formed because the coating spreads uniformly on the surface of the casting and penetrates into surface microvoids, e.g. formed by the removal of surface sand and graphite (Fig. 9 E).

Figure 8. Electrolytic cleaning of cast iron with molten salt — D) After final reduction cycle

Figure 9. Electrolytic cleaning of cast iron with molten salt — E) After brazing and babbitting

2.2.4. Coatings Removal

Numerous coatings are applied to metal substrates for engineering and aesthetic purposes. Coatings (e.g., plasma- or flame-sprayed tungsten carbide and chromium carbide) are used to impart desired wear- and erosion-resistant characteristics to critical components. If these coatings must be removed, conventional chemical methods (see Section 2.1) are often inadequate because the coatings are resistant to aqueous solutions; mechanical methods are labor-intensive, and the coatings are difficult to remove because of their wear-resistant characteristics. Molten salt baths can react with the metal or the carbide fractions of these coatings, and remove them.

Tungsten carbide, for example, reacts with an oxidizing molten salt to form alkali metal tungstates and carbonates:

$$\mathrm{WC}_x + (\mathrm{Na,K})\,\mathrm{OH} + \mathrm{NO}_3^- \rightarrow (\mathrm{Na,K})_2\mathrm{WO}_3 + \mathrm{NO}_2^- + \mathrm{H}_2\mathrm{O} + (\mathrm{Na,K})_2\mathrm{CO}_3$$

Similar reactions occur with other commonly used coatings such as chromium carbides.

Removal of organic coatings such as paints and polymers relies on the oxidizing potential of molten salts to provide controlled chemical "combustion". The molten salt acts as a heat source to initiate the reaction, and as a heat sink that absorbs excess heat from the exothermic reaction of the organic materials being removed. These properties help to prevent localized overheating of the components being cleaned and assure complete removal without the formation of carbonaceous chars or soot. Typical uses for salt bath paint removal include both salvage stripping of rejected coated components and maintenance stripping of carriers, hooks, fixtures, and racks from production coating lines. The stripping operation may be carried out batchwise or continuously by integrating the stripping system into the production coating line.

Removal of solidified polymer residues is an important application for molten salt bath cleaning in the synthetic-fiber industry. The molten polymer is extruded through an orifice plate known as a spinneret. The dimensions and geometry of the spinneret holes are critical for the consistent production of a quality fiber, and represent a significant capital investment on the part of the fiber producer. Conventional thermal

cleaning methods such as incineration or burnoff can result in metallurgical damage from localized overheating. Molten salt bath cleaning prevents localized overheating during the polymer removal process and allows the spinneret to be cleaned without any adverse affects on performance [14].

3. Phosphating

Phosphating is the process of coating a metal surface with a layer of insoluble metal phosphates by treating it with an acidic phosphate-containing solution [15 – 20]. Zinc, iron, and manganese phosphate coatings are most common. The phosphate coating, specified as a conversion coating owing to the coating mechanism, provides an excellent base for paints, oils, or cold-forming lubricants. Iron and steel, steel coated with zinc or zinc alloys, and, to a lesser extent, aluminum alloys are the most common substrates.

Phosphating is used in the metalworking industry all over the world. Thus, virtually all passenger cars are zinc phosphated prior to painting; cold extrusion of steel would not be economically feasible without phosphating.

Phosphating chemicals are proprietary; major suppliers include Chemetall, Henkel, Nihon Parkerizing, Nippon Paint, and PPG.

3.1. Chemistry

Table 2 presents a collection of phosphating processes and phosphate coatings. The chemical basis for all of these processes is similar and will be exemplified in more detail for zinc phosphating.

Reaction Steps in Zinc Phosphating. Phosphating solutions are applied either by spraying or immersion (dipping).

Essential constituents of a zinc phosphating solution are zinc, phosphate ions, and an oxidizing agent (Ox), often sodium nitrite. The pH value is between 2 and 3.5. Concentrations vary considerably; additives such as nitrate, fluoride, silicofluoride, nickel ions, or manganese ions are common. As an example, the following approximate bath composition is suitable for the phosphating of steel sheets as a pretreatment prior to painting: Zn^{2+} 1.2 g/L; Ni^{2+} 0.1 g/L; H_3PO_4 + $H_2PO_4^-$ 15 g/L; and NO_2^- 0.1 g/L.

The pH of the solution is adjusted to 3.2 with sodium hydroxide. The process is usually carried out at up to 95 °C. For cold forming applications total concentrations may well be ten times higher.

In the ideal case, the phosphating reaction can be broken down into five steps:

Pickling reaction

$$Fe + 2\,H^+ \rightarrow Fe^{2+} + H_2 \text{ for Fe} \tag{1}$$

$$Zn + 2\,H^+ \rightarrow Zn^{2+} + H_2 \text{ for Zn} \tag{2}$$

$$AlOOH + 3\,HF \rightarrow Al^{3+} + 3F^- + 2\,H_2O \text{ for Al} \tag{3}$$

$$Al + 3\,H^+ \rightarrow Al^{3+} + 3/2\,H_2 \text{ for Al} \tag{4}$$

Acceleration

$$H_2 + 2\,Ox \rightarrow 2\,HOx \tag{5}$$

$$Fe^{2+} + H^+ + Ox \rightarrow Fe^{3+} + HOx \text{ for Fe} \tag{6}$$

Complex formation

$$Al^{3+} + 6\,F^- \rightarrow AlF_6^{3-} \text{ for Al} \tag{7}$$

Coating formation

$$3\,Zn^{2+} + 2\,H_2PO_4^- + 4\,H_2O \rightarrow Zn_3(PO_4)_2 \cdot 4\,H_2O + 4H^+ \tag{8}$$

$$2\,Zn^{2+} + Fe^{2+} + 2\,H_2PO_4^- + 4\,H_2O \rightarrow Zn_2Fe(PO_4)_2 \cdot 4\,H_2O + 4\,H^+ \tag{9}$$

Sludge formation

$$Fe^{3+} + H_2PO_4^- \rightarrow FePO_4 + 2\,H^+ \text{ for Fe} \tag{10}$$

$$AlF_6^{3-} + 3\,Na^+ \rightarrow Na_3AlF_6 \text{ for Al} \tag{11}$$

Pickling Reaction. Part of the metal surface is dissolved by the acid. The phosphating of aluminum requires fluoride ions to attack surface oxides which only slowly dissolve in phosphoric or nitric acid.

Acceleration. The pickling reaction is accelerated by oxidizing agents (Ox) called accelerators (Table 3), which also prevent the evolution of excessive amounts of molecular hydrogen (Eq. 5), thus minimizing the danger of hydrogen embrittlement.

Table 2. Phosphating processes and coatings

Phosphating process	Cations in the phosphating solution*	Phosphate coating		Coating weight, g/m ^{2}	Substrate
		Composition	Mineralogical name		
Zinc phosphating	Zn^{2+} (Fe^{2+})	$Zn_3(PO_4)_2 \cdot 4\,H_2O$	hopeite	1.3 – 40	Fe, Zn, Al
		$Zn_2Fe(PO_4)_2 \cdot 4\,H_2O$	phosphophyllite	1.3 – 40	Fe
	(Ni^{2+}, Mn^{2+})	$Zn(Ni, Mn, Zn)_2(PO_4)_2 \cdot 4\,H_2O$	isotypic hopeites	1.3 – 15	Fe, Zn, Al
